(Dated: November 7, 2023)

Self-propelling active matter relies on the conversion of energy from the undirected, nanoscopic scale to directed, macroscopic motion. One of the challenges in the design of synthetic active matter lies in the control of dynamic states, or motility gaits. Here, we present an experimental system of self-propelling droplets with thermally controllable and reversible dynamic states, from unsteady over meandering to persistent to arrested motion. These states depend on the Péclet number of the molecular process powering the motion, which we can tune by using a temperature sensitive mixture of surfactants as a fuel medium. We quantify the droplet dynamics by analysing flow and chemical fields for the individual states, comparing them to canonical models for autophoretic particles. In the context of these models, we experimentally observe, in situ, the fundamental first broken symmetry that translates an isotropic, immotile base state to self-propelled motility.

Active matter is defined by the nonlinear conversion of free energy on the molecular scale into macroscopic dynamics - which means that small changes in molecular processes can crucially tip the overall system into a different area in phase space, corresponding to often counter-intuitive dynamical state changes.

It is easy to move agents by external fields: with some more effort we can have them convert free energy on the molecular scale into self-propelled, autonomous motion. However, like a sorcerer's apprentice [1] we find that stopping this motion is not a trivial task; after all, one is required to deplete an energy reservoir or reverse a dynamic instability.

This kind of control is important in the design and study of artificial and biological microswimmers, their theoretical modeling, experimental realization, and, ultimately, to provide design principles and dynamic control for technological application. Autophoretic particles [2–5] and, particularly, their experimental counterpart, active droplets [6–15], are popular active matter models driven by purely physicochemical mechanisms. Generally, their dynamics are characterized by a dimensionless Péclet number Pe , quantifying the ratio of advective and diffusive transport of chemical fuel [16]. With increasing Pe , autophoretic particles first transition from *passive* isotropic chemical conversion to *active* self-propulsion, and further from persistent to unsteady motion via a sequence of broken symmetries and interfacial flow modes of increasing complexity [14, 16–21].

Recent studies have investigated the control of speed and dynamic states of such microswimmers in response to externally applied stimuli such as temperature [22, 23] or illumination [24–30]. On heating, physical intuition

suggests that motion should accelerate and destabilize, either by the increase of translational and rotational diffusion with decreasing viscosity, or by increased activity from the molecular thermodynamics driving the motion. However, the nonlinear dynamics of self-organized activity can drive counter-intuitive effects, as we have previously found for active droplets which destabilize with increasing viscosity due to an associated increase in Pe [20].

In this study, we explore a counter-intuitive response to increasing temperature. We study active droplets using a temperature sensitive combination of co-surfactants as a fuel medium. We reversibly control the transition between three distinct dynamic states from unsteady to oscillatory to steady, straight swimming to eventual arrest with increasing ambient temperature. Notably, we are able to control Pe to experimentally observe the fundamental first symmetry breaking of the inactive isotropic base state into directed self-propulsion in both chemical and hydrodynamic fields.

I. RESULTS

A. Self-propelling droplets in co-surfactant solutions

Our experimental system consists of oil droplets (CB15) immersed in an aqueous solution of the ionic surfactant tetradecyltrimethylammonium bromide (TTAB) at 9–15 wt% (267–445 mM) and the triblock copolymer Pluronic F127 (PF127) at 4 wt%, or 3 mM.

CB15 droplets self-propel reliably in supramicellar solutions of pure TTAB above 5 wt% [20, 32]. Briefly put, the swimming is due to oil diffusing from the droplet into TTAB micelles [13, 15, 18], which removes surfactant from the droplet posterior, while the anterior is replenished by the advection of fresh surfactant (Fig. 1b).

* c.c.maass@utwente.nl

FIG. 1. **Schematics of the experimental setup and droplet propulsion mechanism.** (a) With increasing/decreasing temperature, there is an increased/decreased affinity for TTAB to form mixed micelles with PF127. Simplified aggregation schematic (cf. [31]). (b) Droplet propulsion during solubilisation: an inhomogeneous distribution of empty TTAB micelles causes a self-sustaining Marangoni gradient at the oil-water interface. (c) Setup: The droplet (diameter 50 μm) swims in a quasi-2D (13 mm \times 8 mm \times 50 μm) cell on a temperature controlled microscope stage.

The key point here is that the empty micelles at the anterior are more thermodynamically stable than the oil-filled ones at the posterior [18, 33]: in consequence the critical micelle concentration is higher in front of a moving droplet. The resulting self-enhancing surface tension gradient drives the droplet forward until it is dissolved. Typically, a CB15 droplet of diameter 50 μm will swim in 5 wt% TTAB for 1-2 hours. Thus, empty TTAB micelles serve as fresh, and oil-filled ones as spent fuel. Based on this mechanism, one can define a Pe of droplet motion that increases with viscosity, droplet size and surfactant concentration, i.e. chemical activity [14, 18, 20, 21, 34].

PF127 is a nonionic, triblock copolymer surfactant that in a pure aqueous solution forms micelles with a hydrophobic core of propylene oxide (PPO) and an outer shell of hydrated ethylene oxide (PEO) [35–40] above the critical micelle temperature, CMT $\approx 21^\circ\text{C}$ at 4 wt% PF127 [37]. In the presence of ionic co-surfactants like TTAB, which bind strongly with PF127, mixed TTAB/PF127 aggregates form (Fig. 1a, SI section 3, Figs. S2, S3 and S4), with excess TTAB forming single-species micelles [31, 41–43]. It has been found [42] that the TTAB binding capacity of PF127 is amplified with increasing temperature, due to an increasing dehydration of the PPO blocks (hydrophobic effect [35, 44]).

Under our experimental conditions, we expect a significant coverage of TTAB at the interface (SI Fig. S5). Furthermore, CB15 droplets are completely immotile and hardly solubilize in pure PF127 solutions (SI Fig. S6), while in a mixed TTAB/PF127 medium self-propelling at speeds $\approx 20 \mu\text{m/s}$, comparable to experiments in pure TTAB solutions (cf. [20, 32] and SI Fig. S7). We therefore regard TTAB as the primary surfactant involved in the solubilization and the interfacial gradients driving the droplet motion. This activity is controlled by PF127 binding and relasing TTAB micelles in the bulk medium (Fig. 1a,b). Thus, the Péclet number Pe of droplet activity *decreases* with *increasing* temperature, as an increasing fraction of TTAB is bound in mixed micelles.

According to literature on the composition of PF127/TTAB aggregates [41, 42, 45], the amount of bound TTAB in our swimming medium should exceed 1 wt% and further increase with temperature, which is on the order of the amounts required ($< 5 \text{ wt}\%$) to suppress droplet motility [15, 20], as observed in the experiments we show below (see also Fig. S1). We further note that the swimming medium is Newtonian, with only weakly temperature dependent viscosity (SI Fig. S8).

B. Swimming dynamics controlled by temperature and fuel concentration

We begin with an overview of the general swimming dynamics taken from wide-field video microscopy under changing the ambient temperature, and for a range of TTAB concentrations. The setup contains a quasi-2D microfluidic cell on a temperature controlled stage (Fig. 1c). Fig. 2a (Movie S1) plots a trajectory colour-coded once by speed and once by temperature, recorded at a set heating/cooling rate of 1 K/min, using a swimming medium containing 10 wt% TTAB.

We start at $T \approx 15^\circ\text{C} < \text{CMT}$. Below $T_{\text{straight}} = 22^\circ\text{C}$, the droplet meanders. Above, the motion is straight, gradually slows down and eventually stops at $T_{\text{stop}} \approx 27^\circ\text{C}$. During a subsequent cooling ramp, the droplet remains immotile down to a significantly lower temperature $T_{\text{start}} \approx 17^\circ\text{C}$, where it abruptly starts to meander again.

As well as by temperature, the swimming dynamics are also susceptible to the TTAB concentration. Previous studies on single-surfactant systems found a transition from straight to reorienting to unsteady swimming [18, 34] in response to an increase in fuel surfactant. This increase corresponds to increased Pe , leading to the emergence of destabilising higher order modes in the interfacial flow and chemical fields, as predicted by canonical models for isotropic autophoretic particles [10, 16, 46].

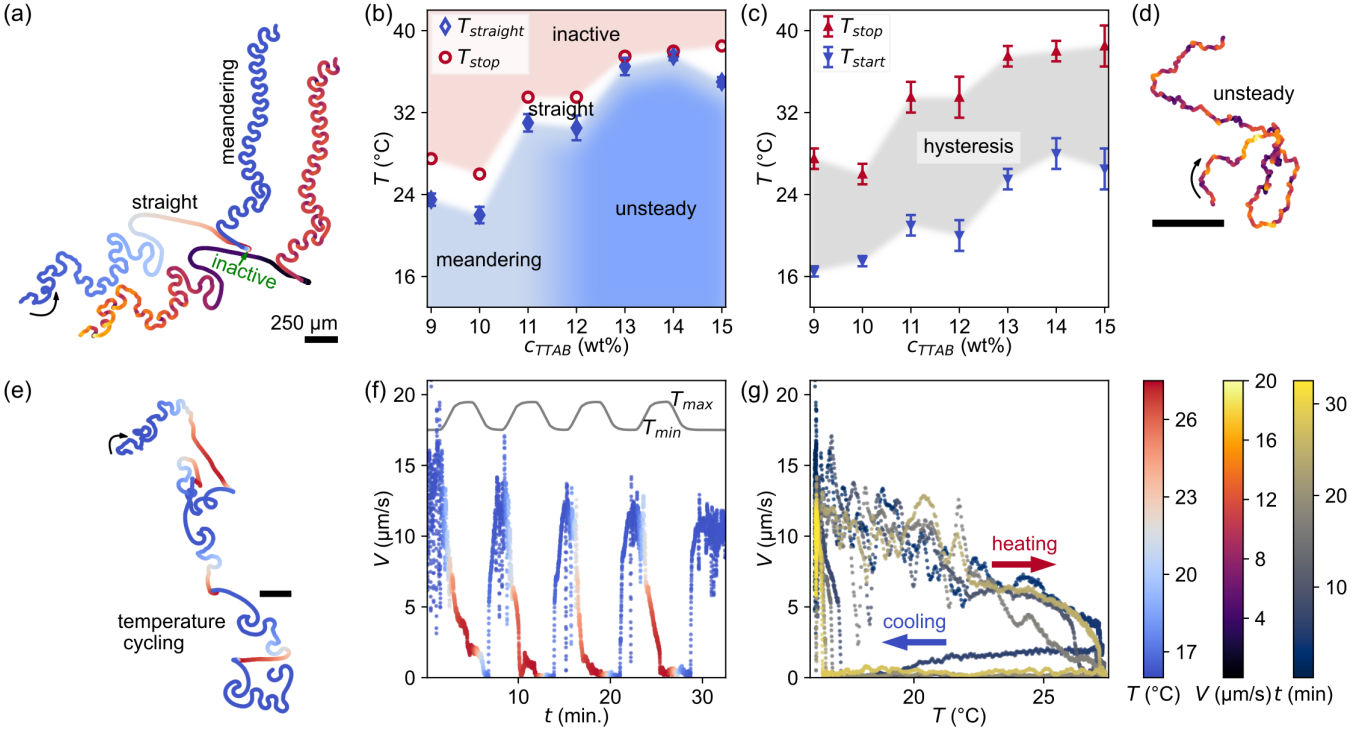

FIG. 2. Swimming dynamics controlled reversibly via temperature and fuel concentration (a) Droplet trajectory transitioning from meandering to straight swimming to arrest during a heating and subsequent cooling ramp with a set rate of 1 K/min in a mixed surfactant swimming medium, color coded by droplet speed and recorded temperature. See also Movie S1. Color map and scale bars (250 μm) apply to all figures in the paper, and concentrations for PF127 and TTAB are always 4 wt% and 10 wt%, respectively, unless stated otherwise. (b) Map of the swimming dynamics depending on temperature and surfactant concentration. (c) Hysteresis between droplet stop and start transition temperatures. Error bars also apply to T_{stop} in (b); experiments done in triplicate with 5–10 droplets each. (d) Example of unsteady motion at 15 wt% TTAB and 21 °C (see also Movie S2). (e) Droplet trajectory during multiple heating/cooling cycles set at 10 K/min and 10 wt% TTAB. See also Movie S3. (f) Corresponding droplet speed vs. time, with inset plot of the recorded temperature ramps. (g) Droplet speed vs. recorded temperature showing a hysteresis in the re-onset of motion during cooling: the arrest during cooling is extended, with a sudden recovery of the initial speed at $T \approx 17^\circ\text{C}$.

At low temperatures, the presence of a co-surfactant does not change these dynamics, as we find a transition from meandering to unsteady motion (Fig. 2d, Movie S2) with increasing TTAB concentration. We have summarized these swimming dynamics in a map spanned by temperature and surfactant concentration in Fig. 2b. With increasing temperature, we observe a universal transition via straight swimming to eventual arrest. We posit that the temperature dependent TTAB depletion lowers Pe below the critical thresholds of higher order interfacial modes, down to $n = 1$ for straight swimming and finally $n = 0$, below the fundamental advection-diffusion instability. We do not provide a quantitative estimate of Pe following [20], as we cannot quantify the temperature dependence of the underlying physical chemistry parameters. Fig. 2b also shows the transition temperatures to increase with TTAB concentration: for the droplet to arrest, more TTAB needs to be removed from the swimming medium. We found the stop/start hysteresis for all TTAB concentrations in use (Fig. 2c).

These state transitions are well reversible with temperature, up to some slowdown attributable to droplet shrinkage. The experiment shown in Fig. 2e-g and Movie S3 was recorded at a faster rate of 10 K/min to permit multiple heating and cooling cycles, with dynamics similar to the system cooled at slower rates. Fig. 2e and f show the droplet trajectory color coded by temperature and a corresponding plot of speed over time. The initial motion is recovered after each heating and cooling cycle, apart from a very gradual decrease in maximum speed which we may attribute to droplet shrinkage. We have further analyzed speed versus temperature in Fig. 2g), and found a hysteresis cycle with a delayed re-onset of motion reproducible over multiple heating/cooling ramps.

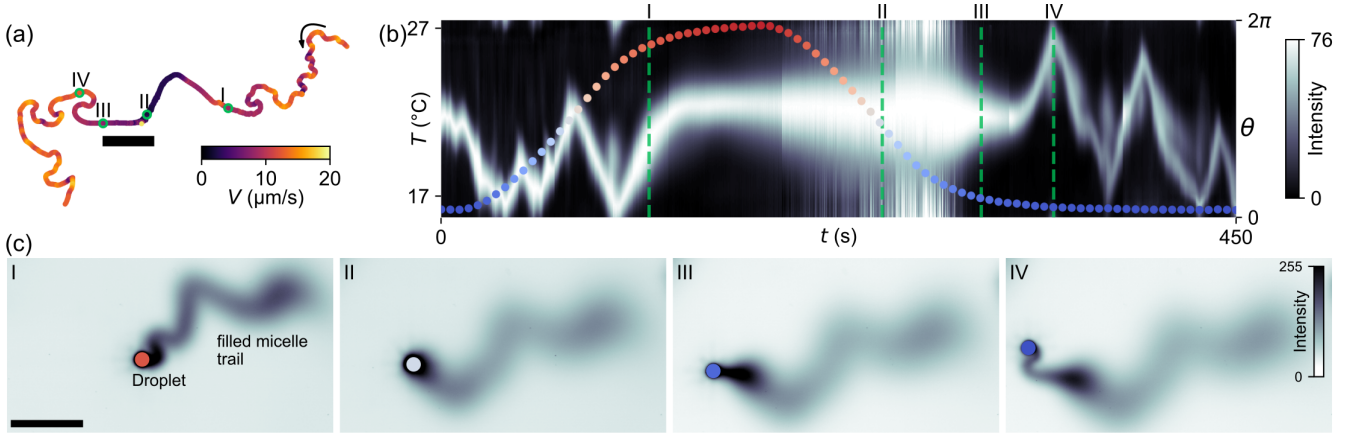

FIG. 3. **The hysteresis in the re-onset of droplet motion is caused by spent fuel aggregation.** (a) Droplet trajectory during heating and subsequent cooling ramp color coded by speed. (b) Kymograph showing the evolution of chemical concentration field around the droplet interface and the recorded temperature (colored symbols). (c) Snapshots of droplet chemical trails at different temperatures as marked by I-IV in (a) and (b). See also Movie S4. 250 μm scale bars and colour maps as defined in Fig. 2.

C. Chemical and flow fields

We continue with a discussion of the chemical dynamics during the droplet arrest, to motivate the hysteresis in the re-onset of motion; and of the corresponding flow field to investigate the interfacial mode evolution.

The field of spent chemical fuel affects the interfacial Marangoni gradients driving the droplet [18, 20, 47]. We visualise it by doping the droplet with the fluorescent dye Nile Red [48], which co-moves with the oil phase into the filled micelles, and extracting the fluorescence intensity I under videomicroscopy (Movie S4). In Fig. 3, we analyze the chemical dynamics for one droplet during a heating and cooling cycle, by a speed-coded trajectory (a), a kymograph of I around the droplet perimeter, θ vs. time and recorded temperature (b), and with micrographs at the times marked I-IV (c).

During heating, the droplet transitions from unsteady to straight swimming to immotility (Fig. 3a). We note that this particular experiment featured some global drift causing translation even in the immotile state (see Movie S4). In the kymograph (Fig. 3b), at $T < 26^\circ\text{C}$, the band corresponding to the chemical trail translates in the angular space due to the reorientation of the droplet (I). At $T \approx 26^\circ\text{C}$, the droplet slows down and comes to a halt. As the system is cooled down to $T \approx 21^\circ\text{C}$, the inactive droplet still solubilises isotropically, and oil-filled micelles accumulate around the perimeter θ . Correspondingly, the band in the kymograph widens over the entire angular space (II). The accumulated filled micelles block empty micelles from reaching the interface [47, 49], such that in the presence of oil-filled micelles even more mixed micelles need to disintegrate to restart activity. Thus, the motility transition temperature is lowered, here to $T_{\text{start}} = 16.8^\circ\text{C}$, where the droplet escapes the oil-filled micelle cloud (III) and swims away (IV).

Before discussing the flow fields, we note two more consequences of oil saturation. First, the hysteresis in Fig. 2c) can be reduced (e.g. to approximately half of $T_{\text{stop}} - T_{\text{start}}$ at 13 wt% TTAB) if the system is not heated to full inactivity, but it is never entirely suppressed. This can be understood as follows: during the late stage of the heating ramp, the droplet is already dispersing oil into its local environment by recirculation, starting from the posterior - an effect we have also found in self-throttling pumping droplets in [47]. During heating, the droplets will come to a stop even before activity has fully ceded (see the discussion of Fig. 4b below), and self-propulsion would always need to restart from inside an oil-rich region as shown in Fig. 3c-II.

The regime of straight swimming appears to be highly localized on cooling (Movies S1 and S6): the droplet switches after a few seconds to a meandering motion (Movie S1). We argue here that outside the strongly localized cloud of spent fuel (see Movie S4 and Fig. 3c), more empty TTAB micelles have been released, such that the droplet experiences a higher Pe once it escapes its self-generated local trap.

To analyze the mode evolution causing arrest and sudden onset of motion during heating and cooling (Movie S5), we added tracer colloids to the oil phase, performed high resolution bright field videomicroscopy and analyzed the internal flow field $\mathbf{u}(x, y)$ by particle image velocimetry (PIV). Fig. 4b shows the evolution of \mathbf{u} with increasing temperature. At $T = 16^\circ\text{C}$, we see a mixed dipolar and quadrupolar flow field (modes $n = 1, 2$) corresponding to the meandering trajectory in Fig. 2a [20, 21]. At even higher temperature, $T = 21^\circ\text{C}$, the droplet swims straight, Pe decreases and the flow field is purely dipolar ($n = 1$). As the droplet begins to slow down, an inactive region spreads from the droplet posterior ($T = 24^\circ\text{C}$). Finally ($T = 27^\circ\text{C}$), just before the droplet stops ($n = 0$), only a small region at the droplet anterior

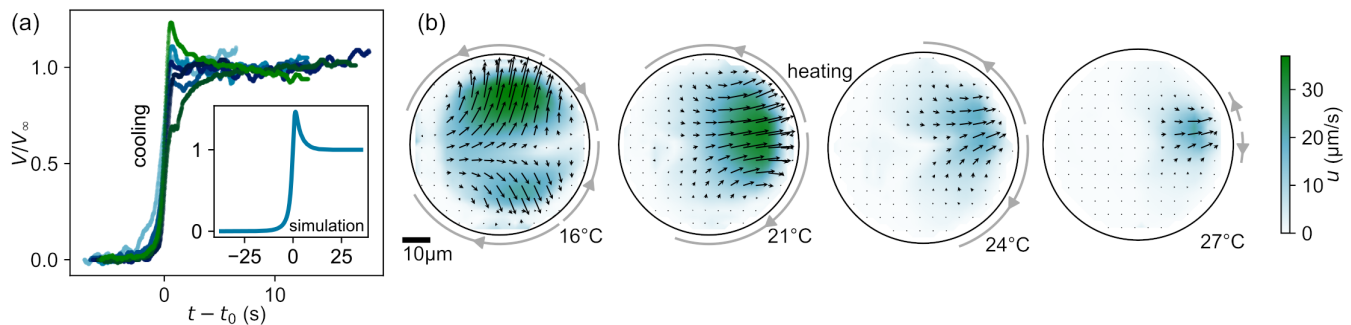

FIG. 4. **Observation of the fundamental transition between passive dissolution and active propulsion.** (a) Onset of motion during re-cooling, speed (normalized to final speed V_∞) vs. time for multiple runs with t_{onset} set to the point of maximum acceleration. Inset: simulation for an isotropic autophoretic particle under comparable conditions ($H = 2.2R$ confinement, $Pe = 8$), following [16, 50]. See also Movie S6. (b) Internal flow field with increasing temperature, starting at a mixed dipolar/quadrupolar mode (meandering), over a purely dipolar mode (straight) that recedes to the anterior (slowdown). Vectors and color map inside the droplet indicate the velocity field $\mathbf{u}(x, y)$; arrows around the perimeter mark the active regions on the droplet interface. Scale bar $10 \mu\text{m}$.

is active [47]. As shown in Fig. 3II, the local environment isotropically saturates with spent fuel while the droplet is immotile.

The gradual increase of Pe during cooling now allows us to directly observe the fundamental first transition from the immotile base state to self-propelled motion [10, 16]. This can be realised theoretically using hydrodynamic models, originally proposed in [16] as follows:

A spherical particle of radius R is immersed in a fluid medium containing a chemical fuel at concentration c . At negligible Reynolds numbers, the flow is governed by the Stokes equations, $\mu \nabla^2 \mathbf{u} = \nabla p$, $\nabla \cdot \mathbf{u} = 0$. The chemical field is coupled by an advection-diffusion equation,

$$|Pe| \left(\frac{\partial c}{\partial t} + \mathbf{u} \cdot \nabla c \right) = \nabla^2 c, \quad Pe \equiv \frac{\mathcal{A}MR}{D^2}, \quad (1)$$

and by the particle consuming fuel at its boundary, $\partial_t c(R) = -\mathcal{A}$. The Péclet number is set by the activity \mathcal{A} , mobility \mathcal{M} and diffusivity D of the chemical species and the particle radius R . Using a decomposition into squirmer modes and a linear stability analysis around the isotropic base state (mode $n = 0$), the authors find a transition to the propulsive dipolar state ($n = 1$) above a threshold value of $Pe = 4$.

Our mixed surfactant method allows us to observe the growth of the bipolar mode in situ and a detailed comparison with the theory. We recorded the droplet speed V at the onset of motion and performed a simulation of the interfacial instability, solving for the full 3D problem following [16, 50] and adapted to our cell geometry (see SI section 9), with good qualitative agreement between experimental and numerical data (Fig. 4a, Movie S6).

II. CONCLUSIONS

We show that controlling the dynamics of self-propelling droplets by micelle mediated interactions [51, 52] provides a promising framework to regulate active droplet dynamics: we can now control self-propulsion from an unsteady or meandering state over quasi-ballistic propulsion to full arrest without needing to change the chemistry of the system. The transitions are almost fully reversible, excepting a slight reduction in peak speed that can be attributed to droplet shrinkage.

Our hypothesis – fuel binding by thermosensitive polymer cosurfactants – does not include the behavior of adsorbed polymer at the interface, which might also be temperature dependent. However, we argue that these effects are, if present, secondary to the binding and release of TTAB in the swimming medium: generally, the desorption kinetics of large polymers are assumed to be exceedingly slow [44]. Thus, if these kinetics were the main drivers of thermoresponsive mode switching, it would not be consistent with our observations of cyclic reversibility and the fast response to changed external conditions, i.e. the onset of motion in Fig. 4a and particularly the fast, local adaptation to the fuel-rich medium outside the saturation area.

Our experiments fit into the framework of the canonical theory for autophoretic particles, where the observed dynamic regimes correspond to interfacial modes becoming unstable with increasing or decreasing Péclet number.

While such higher order modes have been documented individually, the fundamental spontaneous transition from an isotropic zero order base state to a first order propulsion state is hard to observe experimentally, as the setup of the experiment usually provides sufficient disturbances to instantaneously set off droplet motion. By a non-invasive temperature driven crossing of the critical Pe threshold, this is now possible, and, as we

have demonstrated by chemical and flow signatures, even quantifiable.

Acknowledgements, Author contributions, and data availability

We thank Dr. Babak Vajdi Hokmabad and Dr. Stefan Karpitschka for invaluable advice and discussions, Dr. Stephan Weiss for providing the thermistor and Dr. Kris-

tian Hantke for experimental support.

PR designed and performed experiments, analyzed data and wrote the paper, Rå and SV performed experiments and analyzed data, YC designed and performed simulations, MJ designed experiments, CCM designed and performed experiments, analyzed data and wrote the paper. All authors proofread the paper.

The data supporting the findings of this study and the numerical code underlying Fig. 4a are available at DOI:10.5281/zenodo.7818660.

1. MATERIALS AND CHARACTERIZATION

We obtained CB15 (Synthon Chemicals), TTAB and PF127 (Sigma-Aldrich) and used them as-is. To study the influence of mixed micelles on active droplet motility around room temperature, we varied the TTAB concentration between 9–15 wt%. We note that a low concentration of PF127 requires heating the system to high temperatures to deplete TTAB, causing evaporation issues, while at a higher concentration of PF127 droplets would only be active at low temperatures. This strongly limited the experimentally accessible parameter space for PF127, and we opted to keep the concentration fixed at 4 wt%. An overview of the media compositions for which we observed swimming at room temperature (22 °C) is shown in Fig. S1. Increasing the amount of PF127 suppresses motility, while an excess of TTAB promotes it. The typical molarity ratios for motility are of the order of 1:100.

FIG. S1. Motility chart for 50 µm droplets in media of various surfactant composition, taken at room temperature.

* c.c.maass@utwente.nl

2. MICROFLUIDIC EXPERIMENTS

We mass produced CB15 droplets in microfluidic flow focusing devices [20] at a size of $(50 \pm 5) \mu\text{m}$. We fabricated the experimental reservoir, a Hele-Shaw geometry, by spin coating a 50 µm layer of SU-8 photoresist on glass, and creating a rectangular void space of area $(13 \times 8) \text{ mm}^2$ by UV photolithography. For experiments, we filled it with a dilute droplet emulsion and sealed it with a glass cover slip.

We recorded the motion of active droplets on a bright-field microscope (Olympus IX-81) with a temperature controlled stage (Linkam PE100) which allowed for both heating and cooling protocols. We set the reservoir temperature at the desired initial value for a period of 5 min, after which we started measurements.

We performed temperature ramp experiments with a set heating/cooling rate of 1 K/min or 1 K/min. As shown in Fig. 2 (c), the system did not equilibrate instantaneously. We therefore directly measured the sample temperature using a thermistor taped to the top plate of the microfluidic reservoir (Fig. 1). Movie frames were recorded at 4 frames per second (fps) using a Canon digital camera (EOS 600d) with a digital resolution of 1920 x 1080 px.

To estimate whether the quasi 2D confinement affects the observed dynamics, we have also recorded the temperature-dependent droplet motion in reservoirs with a larger height of 310 µm and 2 mm, using a swimming medium with 10 wt% TTAB and 4 wt% PF127. We found similar dynamic states and, within the experimental error (see Fig. 2b), the same transition temperatures ($T_{\text{straight}} \approx 23^\circ\text{C}$, $T_{\text{stop}} \approx 27^\circ\text{C}$) as in the case of the quasi-2D geometry, $h = 50 \mu\text{m}$ (Fig. 2b).

3. INVESTIGATION OF TTAB/PF127 MICELLE FORMATION

To investigate the formation of individual and mixed micelles in our particular swimming medium, we recorded dynamic light scattering and calorimetry data on solutions of pure and mixed surfactants. The nature of these complexes is according to existing literature highly dependent on concentrations and temperature, however, at

the relative concentrations exceeding 1:100 in our system, PF127 micelles are presumably fully broken down for the entire temperature range under investigation [42]. For this reason, we do not expect the CMT of PF127 to be a characteristic quantity in the dynamics of our system.

A. DLS measurements

We performed dynamic light scattering (DLS) measurements for the co-surfactant mixtures used in our experiments on a Malvern Zetasizer Ultra Red. We placed a 1 mL sample in a polystyrene cuvette and recorded the backscattering intensity at 173° between 15°C and 30°C . At each temperature, the sample was allowed to equilibrate for 120 s, and all measurements were carried out in triplicate. We have plotted the size distributions for selected temperatures in Fig. S2 and summarized the temperature dependent behaviour for all samples via the Z average hydrodynamic diameter, i.e. the “intensity weighted mean hydrodynamic size of the ensemble collection of particles” (Malvern) in Fig. S3. For 4 wt% PF127, there is a significant increase in diameter above 23°C , corresponding to the formation of PF127 micelles (we note that this appears somewhat higher than the CMT $\approx 21^\circ\text{C}$ literature value [35, 37]). This increase is suppressed in the presence of TTAB, consistent with the formation of PF127/TTAB complexes seen in literature [31, 41, 42, 53]. We note that, from the Z average, the hydrodynamic diameter of these complexes is somewhat smaller than that of a PF127 monomer, which is in line with existing studies [53]. Further, these complexes appear to be close in size to pure TTAB micelles in a size range $< 5\text{ nm}$ near the lower DLS resolution limit, such that the two species probably cannot be resolved in Fig. S2.

B. Differential scanning calorimetry

We investigated the temperature dependent PF127 micellization using differential scanning calorimetry (DSC). For the measurements, we prepared three sample types: (1) PF127 in 4 wt% water, (2) PF127 4 wt% + TTAB 1 wt% in water and (3) PF127 4 wt% + TTAB 10 wt% in water. Solutions were directly transferred into DSC sample aluminium pans (volume 100 μL , Mettler-Toledo GmbH, Gießen, Germany). DSC pans were covered with aluminum lids. DSC measurements were performed on a DSC 823 instrument (Mettler-Toledo GmbH, Gießen, Germany). Heating-cooling cycles were recorded at a heating/cooling rate of 5 K/min between 0 and 80°C . The measurements were performed under a nitrogen atmosphere with a flow of 30 mL/min . Heating curves were normalized to the sample mass. The endothermic dip in the curve for pure PF127 is consistent with the onset of

micellization from the DLS results, and is similarly suppressed under the addition of TTAB.

4. COSURFACTANTS ON OIL-WATER DROPLET INTERFACES

We conducted further experiments to confirm, under our experimental conditions, (A) that TTAB is the dominant surfactant at the oil-water interface and (B) that the aqueous solubilization of CB15 is mainly TTAB mediated, as follows.

A. TTAB interfacial coverage based on nematic anchoring

In liquid crystal emulsions, the interfacial anchoring of the nematic director depends on the surfactant in use. Assuming comparable interfacial activity for both substances, we can infer the presence of TTAB at the oil-water interface from investigating the anchoring for CB15’s nematic isomer 5CB (at room temperature) under polarised microscopy [54, 55]. We show this in three micrographs in Fig. S5: 5CB droplets (left) in 0.1 wt% TTAB show a cross-shaped interference pattern and a central point defect, consistent with homeotropic (surface normal) anchoring as known for TTAB. On the right, we show a droplet in 0.005 wt% TTAB and 4 wt% PF127, where we observed a bipolar defect pattern, with two opposing defects at the interface (one visible in the micrograph). This pattern is typical for planar anchoring, and we associate it with the large excess of PF127. In the middle image, for 1 wt% TTAB and 4 wt% PF127 (middle), there is only a single point defect, indicating a transition to TTAB mediated homeotropic anchoring already far below the 10 wt% TTAB used in the experiments on motile droplets.

B. Solubilization rate measurements

We measured the shrinking rate of a CB15 droplet for two non-motile cases under bright field microscopy at 63x magnification – 10 wt% TTAB + 12 wt% PF127 and 4 wt% PF127, both at 40°C – and in an ensemble average of motile droplets under typical experimental conditions, 10 wt% TTAB + 4 wt% PDF127 at 20°C under 4x magnification; droplet radii and fitted shrinking rates are shown in Fig. S6. Dissolution is reduced by an order of magnitude without TTAB.

Given that (A) there appears to be a considerable fraction of TTAB at the interface and that (B) droplets neither significantly dissolve or move in pure PF127, we conclude that the droplet motion is primarily driven by TTAB gradients in the oil-water interface, by a mechanism similar to the micellar solubilization driven one known for pure TTAB media [6, 13, 15]. We also note

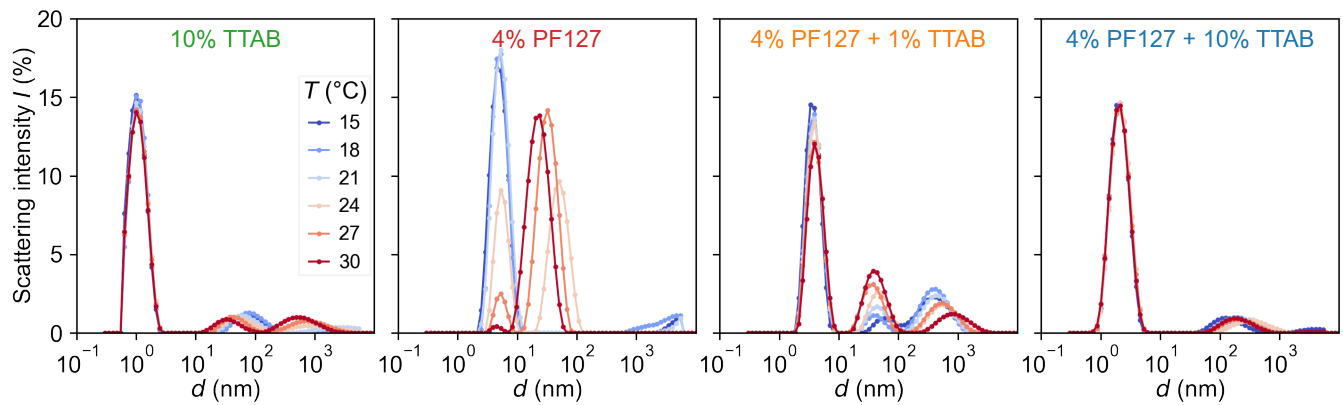

FIG. S2. Dynamic light scattering (DLS) measurements showing the size distributions of four aqueous solutions of PF127 and TTAB with increasing temperature, from backscattering (detector angle 173°). Scattering intensity I vs. hydrodynamic diameter d . Averages over triplicate measurements.

FIG. S3. Intensity weighted Z-average values of the hydrodynamic diameter for each measurement as shown in the DLS series in Fig. S2. The error bars use the standard deviation of the triplicate experimental runs.

FIG. S4. DSC heating curves of PF127 and TTAB solutions. Measurements were performed with a heat rate of 5 K/min and normalized to sample mass.

FIG. S5. Polarized micrographs of 5CB droplets in cosurfactant mixtures: left, 0.1 wt% TTAB, shows homeotropic; right, 4 wt% PF127 and 0.005 wt% TTAB, planar anchoring; middle, 4 wt% PF127 and 1 wt% TTAB, primarily homeotropic. Scale bar 50 μm

FIG. S6. Decrease in CB15 droplet radius over time for non-motile droplets in 4 wt% PF127 (blue) and 12 wt% PF127 + 10 wt% TTAB (orange) media at $T = 40^\circ\text{C}$, and for motile droplets in 10 wt% TTAB + 4 wt% PF127 at 20°C (green, low magnification ensemble average). Dotted lines: linear regression fits to determine the shrinking rates, -0.4 nm/s , -3.5 nm/s and -3.7 nm/s , respectively.

FIG. S7. Temperature dependent droplet dynamics in a solution of pure TTAB at 10 wt%. (a) Droplet trajectory and (b) droplet speed v , and measures of fluctuations in speed, $\langle \Delta v \rangle / \langle v \rangle$, and orientation, $\cos(\Delta\phi)$, over time. With increasing temperature, the droplet motion accelerates and destabilises. Scale bar 250 μm .

that the droplet speed is of a similar order of magnitude as the one in pure TTAB ($\approx 10\text{--}20\ \mu\text{m s}^{-1}$, Fig. S7), such that additional adsorbed PF127 at the interface does not appear to impede the mechanism.

5. TEMPERATURE DEPENDENT DYNAMICS IN PURE TTAB SOLUTION

In Fig. S7, we show a temperature-coded trajectory of a droplet studied under the same conditions as the experiments shown in the main manuscript, but in an aqueous solution of TTAB only at 10 wt%. Here, the motion destabilises with increasing temperature. We illustrate this by temperature-coded plots of three quantities: the speed (top), which increases, but also fluctuates strongly for high temperatures. Further, two simple correlation estimates, both taken over a running time window of $\tau = 2\text{ s}$: the standard deviation over average speed, $\langle \Delta v \rangle / \langle v \rangle$ as a measure of unsteadiness in speed, and the cosine of the angle between $\mathbf{v}(t)$ and $\mathbf{v}(t + \tau)$ via their inner product as a measure of rotational fluctuation. Both indicate strong decorrelation at elevated temperatures. We note that this behavior is strongly different from the one in PF127/TTAB mixtures, where speed and unsteadiness decrease with increasing temperature.

6. VISCOSITY MEASUREMENTS

We measured the viscosity of our swimming media on an Anton-Paar MCR 502 rheometer using a cone-plate geometry with a gap width of 0.1 mm. Measurements were carried out at temperatures between 15 $^{\circ}\text{C}$ and 40 $^{\circ}\text{C}$ and shear rates between 0.1 s^{-1} and 100 s^{-1} (see Fig. S8). We observe Newtonian rheology and an only weakly temperature dependent viscosity. Thus, while

aqueous solutions of PF127 are known to gel at high temperatures, essentially forming a network of micelles, we are still below this non-Newtonian regime at the concentration and temperature range in use.

7. FLOW AND CHEMICAL FIELD MEASUREMENTS

The internal flow field was determined by adding 1 μm diameter tracer Silica particles (Cospheric SiO2MS-1.8) to the oil phase and analysing high magnification videomicroscopy data by particle image velocimetry (PIV). We did not measure external flow fields, since adsorbed PF127 on colloidal tracer particles [56] may cause them to aggregate and impedes accurate PIV measurements.

We recorded videomicroscopy data under a 40x objective using a 4MP camera (FLIR Grasshopper 3, GS3-U3-41C6M-C) at 40 fps at different set temperatures.

To study the sudden onset of motion from an inactive state as the system was cooled, images were recorded at a higher frame rate of 80 fps. Droplet speed over time was calculated from the recorded trajectories.

To visualize the oil-filled micelle chemical trail behind the droplet, we doped the oil phase with Nile Red (Sigma-Aldrich) dye. We performed fluorescent microscopy on an Olympus IX81 microscope with a filter cube (excitation filter ET560/40x, beam splitter 585 LP and emissions filter ET630/75m, all Chroma Technology). Images were captured via a 4x objective using a 4 MP CMOS camera (FLIR Grasshopper 3, GS3-U3-41C6M-C) at 4 fps.

8. DIGITAL IMAGE PROCESSING AND DATA ANALYSIS

We extracted droplet coordinates from bright field microscopy using a sequence of background correction, binarization, blob detection by contour analysis, and minimum enclosing circle fits, and determined trajectories via a nearest-neighbor algorithm using in-house Python scripts building on numpy and opencv. For the strongly overexposed fluorescence data the droplet centroid was calculated via a distance transform algorithm on the fluorescence intensity. The polar intensity map in Fig. 3(b) was derived by taking the intensity in an annular region around the droplet at a distance of 1.2 droplet radii from the centroid [20, 47, 48], as sketched in supporting figure S9.

Using the time-dependent droplet trajectory and temperature data, we estimated transition temperatures between dynamic states. The error bars for temperature in the regime map (Fig. 2f) represent the maximum variation within three different runs on samples containing on the order of 5–10 droplets each. It should be noted that there is some uncertainty associated with estimating T_{straight} and T_{stop} from low magnification droplet trajec-

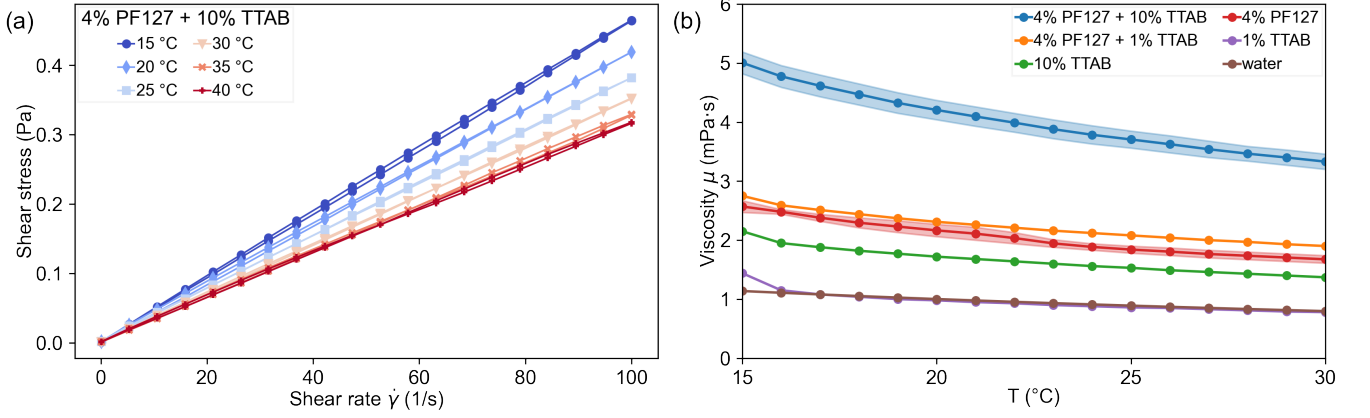

FIG. S8. (a) Shear stress versus shear rates at different temperatures for 4 wt% PF127 + 10 wt% TTAB. (b) Viscosity versus temperature for TTAB and PF127.

FIG. S9. Protocol to extract fluorescence kymographs from microvideo data, by the example of snapshot III from Fig. 3

tory data. As seen in high magnification data in Movie S5, a droplet could appear to be stationary even though it shows internal activity through the motion of tracer particles. Moreover, the transition between a smooth re-orientation and straight motion is somewhat gradual.

We performed PIV analyses using the Matlab PIVlab module [57] with a multi-pass interrogation window of 64×64 pixel and 32×32 pixel with 50% overlap. The spatial resolution of the PIV output was $4.3 \mu\text{m}/\text{px}$.

9. NUMERICS

We simulate a diffusiophoretic particle of unit radius initially located at the center of a domain of size $L_x = 10$, $L_y = 100$, $L_z = 2.2$ with $201 \times 2001 \times 45$ grids at sub-critical Pe . The particle is propelled by diffusiophoresis, a type of microswimmer similar to active droplet, as both move in response to the forces at the surfaces, which depend on the local chemical concentration field (see also [46]). The chemical reaction takes place at the particle surface and whenever there is a chemical concentration difference along the surface, a flow is generated

within the interaction layer near the solid surface, with thickness λ of nanometers, which propels the particle forward.

We use the same non-dimensional governing equations and boundary conditions at the particle interface as those in previous studies [16, 58] (here, solving for the full 3D problem as opposed to the axisymmetric analytical approach). The governing equations are given as

$$\frac{\partial c}{\partial t} + \mathbf{u} \cdot \nabla c = \frac{1}{Pe} \nabla^2 c, \quad (\text{S1})$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\nabla p + \frac{Sc}{Pe} \nabla^2 \mathbf{u}, \quad \nabla \cdot \mathbf{u} = 0, \quad (\text{S2})$$

where c is the concentration, u the velocity. Pe is the Péclet number, which is the ratio of advection to diffusion and Sc is the Schmidt number, which is the ratio between the momentum and mass diffusivities:

$$Pe = \frac{M\alpha L}{D^2}, \quad Sc = \frac{\nu}{D}. \quad (\text{S3})$$

where M is the mobility, $M \sim \pm k_B T \lambda^2 / (\rho \nu)$ with k_B the Boltzmann constant and T the temperature, ρ the density, ν the viscosity, and D is the diffusion coefficient.

The boundary conditions are given as:

$$\partial_n c = -1 \quad u_s = \nabla_s c, \quad (\text{S4})$$

where $\partial_n c$ represents the concentration gradient at the direction normal to particle surface, u_s the slip velocity and ∇_s is the tangential gradient. The top and bottom boundaries (at z direction) of the domain are set as solid walls, and all other domain boundaries (at x and y directions) are set as periodic.

We used a central second-order finite difference scheme to spatially discretize the governing equations, with homogeneous staggered grids used in both the horizontal and vertical directions. The equations are integrated by a

fractional-step method, with non-linear terms computed explicitly using a low-storage third-order Runge-Kutta scheme and the viscous terms computed implicitly by a Crank-Nicolson scheme [59]. For the particle boundary, we make use of the moving least squares (MLS) based immersed boundary (IB) method, where the particle interface is represented by a triangulated Lagrangian mesh [60]. For the detailed numerical methods and validation, we refer to [58].

In simulations, we observed the onset of symmetry breaking for $Pe \gtrsim 6$; the velocity profile in the inset of Fig. 4a is taken from a simulation with $Pe = 8$.

10. SUPPLEMENTARY MOVIE CAPTIONS

Movie S1. Temperature dependent droplet dynamics at 4 wt% PF127 + 10 wt% TTAB, showing a reversible transition from meandering to straight swimming to arrest during a heating and subsequent cooling ramp with a set rate of 1 K/min.

Movie S2. Temperature dependent droplet dynamics at 4 wt% PF127 + 13 wt% TTAB, showing a reversible transition from chaotic to straight swimming to arrest during a heating and subsequent cooling ramp with a set rate of 5 K/min.

Movie S3. Droplet trajectory at 4 wt% PF127 + 10 wt% TTAB, during multiple heating and subsequent cooling ramps at a set rate of 10 K/min.

Movie S4. Fluorescent microscopy visualising droplet chemical trails upon heating and subsequent cooling ramp with a set rate of 5 K/min.

Movie S5. Internal flow visualisation with increasing temperature, starting at a mixed dipolar/quadrupolar mode (meandering), over a purely dipolar mode (straight) that recedes to the anterior (slowdown) and onset of motion during cooling. Excerpts recorded during one continuous experiment, playback (at 40 fps) corresponding to real-time during heating, sped up by 5x during cooling.

Movie S6. Onset of active motion during recooling in a droplet containing tracer colloids, with a superimposed trajectory and the recorded droplet speed V . Experimental duration 18 seconds.
