

Reference Energies for Valence Ionizations and Satellite Transitions

Antoine Marie^{1, a)} and Pierre-François Loos^{1, b)}

Laboratoire de Chimie et Physique Quantiques (UMR 5626), Université de Toulouse, CNRS, UPS, France

Upon ionization of an atom or a molecule, another electron (or more) can be simultaneously excited. These concurrently generated states are called “satellites” (or shake-up transitions) as they appear in ionization spectra as higher-energy peaks with weaker intensity and larger width than the main peaks associated with single-particle ionizations. Satellites, which correspond to electronically excited states of the cationic species, are notoriously challenging to model using conventional single-reference methods due to their high excitation degree compared to the neutral reference state. This work reports 42 satellite transition energies and 58 valence ionization potentials of full configuration interaction (FCI) quality computed in small molecular systems. Following the protocol developed for the QUEST database [Véril et al. *Wiley Interdiscip. Rev.: Comput. Mol. Sci.* **2021**, *11*, e1517], these reference energies are computed using the configuration interaction using a perturbative selection made iteratively (CIPSI) method. In addition, the accuracy of the well-known coupled-cluster (CC) hierarchy (CC2, CCSD, CC3, CCSDT, CC4, and CCSDTQ) is gauged against these new accurate references. The performances of various approximations based on many-body Green’s functions (GW, GF2, and *T*-matrix) for ionization potentials are also analyzed. Their limitations in correctly modeling satellite transitions are discussed.

I. INTRODUCTION

Ionization spectra, probed through techniques like UV-Vis, X-ray, synchrotron radiation, or electron impact spectroscopy, are invaluable tools in experimental chemistry for unraveling the structural intricacies of atoms, molecules, clusters, or solids.^{1–3} Through the positions and intensities of their peaks, these spectra offer key information about the sampled system. For example, these measurements can be realized in various phases (gas, liquid, or solid) and, hence, analyzed to understand changes in electronic structure in these different phases.^{4–7}

Typically, within the energy range from 10 eV to 40 eV, valence-shell ionization occurs, while the core shell is probed at significantly higher energies.⁸ This higher-energy region is not considered in the present study but the concepts that we discuss below in the context of

valence-shell spectra are also encountered in the case of core electron spectroscopy. Particularly, between 10 eV and 20 eV, ionization spectra of small molecules usually exhibit well-defined peaks. These sharp and intense ionization peaks are essentially single-particle processes, *i.e.*, an electron is ejected from the molecule and measured by the detector. These first peaks are associated with outer-valence orbitals. At slightly higher energies, typically several eV, the situation is more complex as, in addition to inner-valence single-particle ionization peaks, additional broader and less intense peaks appear. These are referred to as satellites or shake-up transitions.

In molecules, satellites represent ionization events coupled with the simultaneous excitation of one or more electrons. They are thus intrinsically many-body phenomena, as one must describe at least two electrons and one hole. Satellite transitions can be seen as the equivalent of double excitations in the realm of neutral excitations. Because one must describe processes involving two electrons and two holes, double excitations pose significant challenges for theoretical methods,^{9–11} and the same holds true for satellite transitions. Consequently, such states

^{a)} Electronic mail: amarie@irsamc.ups-tlse.fr

^{b)} Electronic mail: loos@irsamc.ups-tlse.fr

can hardly be described by mean-field formalisms, such as Hartree-Fock (HF) theory. Thus, properly accounting for correlation effects is crucial to describe satellite transitions.¹² In particular, a recent study has emphasized the dynamic nature of this correlation.¹³ In the following the term “ionization” is employed to refer to single-particle processes, also called Koopmans’ states.

Theoretical benchmarks play a pivotal role in evaluating the accuracy of approximation methods.^{14–23} Concerning principal ionization potentials (IPs), which correspond to an electron detachment from the highest-occupied molecular orbital, two prominent benchmark sets are widely recognized: the extensively used *GW*100 test set^{24–26} and a set comprising 24 organic acceptor molecules.^{27–30} Both sets rely on reference values obtained from coupled-cluster (CC) with singles, doubles, and perturbative triples [CCSD(T)] calculations^{31–33} and determined by the energy difference between the neutral and cationic ground-state energies.³⁴ Recently, Ranasinghe *et al.* created a comprehensive benchmark set including not only principal IPs but also outer- and inner-valence IPs of organic molecules.³⁵ Reference values for this set were computed using the IP version of the equation-of-motion (IP-EOM) formalism^{36–40} of CC theory with up to quadruple excitations (IP-EOM-CCSDTQ) for the smallest molecules.³⁵ Note that these benchmarks and the present work deal with vertical IPs, and we shall not address their adiabatic counterparts here.

To demonstrate its predictive capability for valence ionization spectra, an electronic structure method must precisely locate the positions of both outer- and inner-valence ionization potentials, along with valence satellites. However, to the best of our knowledge, no established theoretical benchmarks exist for satellite energies in molecules. Consequently, the primary goal of this manuscript is to establish such a set of values. Finally, it is important to mention that to be fully predictive a method should be able to predict the intensities associated with of these transitions. However, benchmarking intensities is beyond the scope of this work and will be considered in a future study.

Nowadays, a plethora of methods exist to compute IPs in molecular systems. The most straightforward among them is HF where occupied orbital energies serve as approximations of the IPs (up to a minus sign) by virtue of Koopmans’ theorem.⁴¹ Similarly, within density-functional theory (DFT), the Kohn-Sham (KS) orbital energies can be used as approximate ionization energies.^{42–44} The accurate computation of IPs within KS-DFT is still an ongoing research field with, for example, long-range corrected functionals,⁴⁵ KS potential adjusters,^{46,47} double-hybrids functionals,⁴⁸ or even functionals directly optimized for IPs.^{35,49–51} An alternative way to compute electron detachment energies at the HF or KS-DFT levels is through the state-specific self-consistent-field (Δ SCF) formalism, where one optimizes both the neutral ground state and the cationic state of interest, the IPs being computed as the difference between these two total ener-

gies. This strategy has been mainly used to compute core binding energies and is known to perform better than Koopmans’ theorem thanks to orbital relaxation.^{52–58}

Mean-field methods, such as HF and KS-DFT, provide a first approximation to IPs but greater accuracy is often required. The well-known configuration interaction (CI) and CC formalisms provide two systematically improvable paths toward the exact IPs.^{38–40,59} Within both frameworks, IPs can be obtained through a diagonalization of a given Hamiltonian matrix in the $(N - 1)$ -electron sector of the Fock space or through a state-specific formalism similar to Δ SCF. Ranasinghe *et al.* have shown that the mean absolute error (MAE) of IP-EOM-CCSDT with respect to CCSDTQ is only 0.03 eV for a set containing 42 IPs of small molecules.³⁵ Considering the same set, the cheaper IP-EOM-CCSD method has a MAE of 0.2 eV. Recently, the unitary CC formalism has also been employed within the IP-EOM formalism to compute IPs.⁶⁰ As mentioned above, the Δ SCF strategy can be extended to correlated methods which leads to the Δ CC method as an alternative to obtain IPs.⁶¹ Once again, it has been mainly used to compute core IPs but it is also possible to determine valence IPs.^{62–64} Selected CI (SCI)^{65–68} provides yet another systematically improvable formalism for IPs. Indeed, by increasing progressively the number of determinants included in the variational space, one can in principle reach any desired accuracy, up to the full CI (FCI) limit.^{69–75} Recently, the adaptative sampling CI algorithm^{72,76–78} has been used to compute accurate valence ionization spectra of small molecules.¹³

In contrast to the wave function methods previously mentioned, one can also compute IPs via a more natural way based on electron propagators (or Green’s functions), such as the *GW* approximation^{79–81} or the algebraic diagrammatic construction (ADC).^{82,83} The *GW* methodology has a myriad of variants. Its one-shot G_0W_0 version,^{84–90} which was first popularized in condensed matter physics, is now routinely employed to compute IPs of molecular systems and can be applied to systems with thousands of correlated electrons.^{91–103} Other flavors of *GW* such as eigenvalue-only self-consistent *GW* (ev*GW*)^{104–108} and quasi-particle self-consistent *GW* (qs*GW*)^{108–113} have also been benchmarked for IPs. Although the *GW* method is by far the most popular approach nowadays, there exist some alternatives, such as the second Born [also known as second-order Green’s function (GF2) in the quantum chemistry community]^{41,114–129} or the *T*-matrix^{130–147} approximations. However, none of them has enjoyed the popularity and performances reached by *GW*.^{148–150} On the darker side, one of the main flaws of the *GW* approximation is its lack of systematic improvability, especially compared to the wave function methods mentioned above. Various beyond-*GW* schemes have been designed and gauged, but none of them seem to offer, at a reasonable cost, a systematic route toward exact IPs.^{131,132,137,151–168}

The prediction of satellite peaks in molecules garnered attention in the late 20th century. In the 70’s, Schirmer

and coworkers applied extensively the 2ph-TDA [and the closely related ADC(3)] formalism to study the inner-valence region of small molecules.^{12,169–181} CI methods were also employed by other groups to study this energetic region.^{182–193} In both formalisms, the satellite energies are easily accessible as they correspond to higher-energy roots of the ADC and CI matrices. After relative successes for outer-valence ionizations, it was quickly realized that the inner-valence shell is much more difficult to describe due to the overlap between the inner-valence ionization and the outer-valence satellite peaks.¹⁷³ As mentioned above, the satellites present in this energy range cannot be described without taking into account electron correlation at a high level of theory. Even more troublesome, in some cases, the orbital picture (or quasiparticle approximation) completely breaks down. In other words, it becomes meaningless to assign the character of ionization or satellite to a given transition.^{169,173} In the following decades, the symmetry-adapted-cluster (SAC) CI was extensively used to study the inner-valence ionization spectra of small organic molecules.^{194–205} SAC-CI was shown to be able to compute satellite energies in quantitative agreement with experiments while methods based on Green’s functions have been in qualitative agreement, at best.

Satellites, sometimes called sidebands, have been extensively studied in the context of materials.⁷⁹ These additional peaks, which can have different natures, are observed in photoemission spectra of metals, semiconductors, and insulators.^{206–215} In “simple” metals, such as bulk sodium^{206,213} or its paradigmatic version, the uniform electron gas,^{25,214,216–221} satellites are usually created by the strong coupling between electrons and plasmon excitations. It is widely recognized that *GW* does not properly describe satellite structures in solids, and it is required to include vertex corrections to describe these many-body effects. One of the most common schemes to study satellites in solids is the cumulant expansion,^{210,219,222–224} which is formally linked to electron-boson Hamiltonians.^{156,225–227}

Nowadays, computational and theoretical progress allows us to systematically converge to exact neutral excitation energies of small molecules,^{10,73,228–231} and this holds as well for charged excitations like IPs. For example, Olsen *et al.* computed the exact first three IPs of water using FCI,⁵⁹ while Kamiya and Hirata went up to IP-EOM-CCSDTQ to compute highly accurate satellite energies for CO and N₂.³⁹ As mentioned previously, a set of 42 IPs of CCSDTQ quality is also available now.³⁵ Finally, Chatterjee and Sokolov recently computed 27 valence IPs using the semistochastic heatbath SCI method^{73,232,233} in order to benchmark their multi-reference implementation of ADC.^{234,235} They also report FCI-quality energies for the four lowest satellite states of the carbon dimer. The present manuscript contributes to this line of research by providing 42 satellite energies of FCI quality. Additionally, 58 valence IPs are reported as well, among which 37 were not present in Ranasinghe’s CCSDTQ nor Chatterjee’s FCI benchmark set.^{35,234} This study is part of a larger database of highly accurate vertical neutral exci-

tation energies named QUEST which now includes more than 900 excitation energies.^{10,23,230,231,236–242} Our hope is that these new data will serve as a valuable resource for encouraging the development of novel approximate methods dedicated to computing satellite energies, building on the success of benchmarks with highly-accurate reference energies and properties.

II. COMPUTATIONAL DETAILS

The geometries of the molecular systems considered here have been optimized using CFOUR²⁴³ following QUEST’s protocol,^{23,237} *i.e.* at the CC3/aug-cc-pVTZ level^{244,245} without frozen-core approximation. The corresponding cartesian coordinates can be found in the [Supporting Information](#). Throughout the paper the basis sets considered are Pople’s 6-31+G*^{246–252} and Dunning’s aug-cc-pVXZ (where X = D, T, and Q).^{253–256}

A. Selected CI calculations

All SCI calculations have been performed using the configuration interaction using a perturbative selection made iteratively (CIPSI) algorithm^{67,228,257–260} as implemented in QUANTUM PACKAGE.²⁶¹ The multi-state CIPSI calculations are performed by converging several eigenvalues (using the iterative Davidson diagonalization procedure) at each iteration and then selecting determinants for these eigenvectors in a state-averaged way.²⁶² For more details about the CIPSI method and its implementation, see Ref. 261. The frozen-core approximation has been enforced in all calculations using the conventions of GAUSSIAN16²⁶³ and CFOUR,²⁴³ except for Li and Be where the 1s orbital was not frozen.

We followed a two-step procedure to obtain the ionization and satellite energies, I_ν^N , at the SCI level. First, two single-state calculations are performed for the N - and $(N - 1)$ -electron ground states. This yields the principal IP of the system, $I_0^N = E_0^{N-1} - E_0^N$, where E_0^{N-1} and E_0^N are the ground-state energies of the N - and $(N - 1)$ -electron systems, respectively. Then, a third, multi-state calculation is performed to compute the neutral excitation energies of the $(N - 1)$ -electron system, $\Delta E_\nu^{N-1} = E_\nu^{N-1} - E_0^{N-1}$, where E_ν^{N-1} is the energy of the ν th excited states associated with the $(N - 1)$ -electron system. Combining these three calculations, one gets

$$I_\nu^N = E_0^{N-1} - E_0^N + \Delta E_\nu^{N-1} \quad (1)$$

Because single-state calculations converge faster than their multi-state counterparts, the limiting factor associated with the present CIPSI calculations are the convergence of the excitation energies ΔE_ν^{N-1} , and this is what determines ultimately the overall accuracy of I_ν^N .

For each system and state, the SCI variational energy has been extrapolated as a function of the second-order

perturbative correction using a linear weighted fit using the last 3 to 6 CIPSI iterations.^{73,74,264,265} The weights have been taken as the square of the inverse of the perturbative correction. The estimated FCI energy is then chosen amongst these extrapolated values obtained with a variable number of points such that the standard error associated with the extrapolated energy is minimal. Below, we report error bars associated with these extrapolated FCI values. However, it is worth remembering that these do not correspond to genuine statistical errors. The fitting procedure has been performed with MATHEMATICA using default settings.²⁶⁶

The SCI values and their corresponding error bars are reported with three decimal places to enable fair and reliable comparisons between methods, ensuring a precision well below the chemical accuracy threshold (*i.e.* 0.043 eV). One should keep in mind that only the first decimal might be experimentally meaningful (*i.e.*, measured without uncertainty). Finally, note that comparing theoretical and experimental IPs is a complex task, requiring consideration of vibrational effects (see for example Ref. 267) and possibly relativistic effects for inner-valence IP and/or molecules containing third-row atoms.

B. Coupled-cluster calculations

The EOM-CC calculations have been done using CFOUR with the default convergence thresholds.²⁴³ Again, the frozen-core approximation was enforced systematically. IP-EOM-CC calculations, *i.e.*, diagonalization of the CC effective Hamiltonian in the $(N - 1)$ -electron sector of the Fock space,^{36–40} have been performed for CCSD,^{32,36,268–271} CCSDT,^{37,272–274} and CCSDTQ.^{275–279} At the CCSD level, the EOM space includes the one-hole (1h) and the two-hole-one-particle (2h1p) configurations, while the three-hole-two-particle (3h2p) and four-hole-three-particle (4h3p) configurations are further added at the CCSDT and CCSDTQ, respectively. Note that, within the CC formalism, we assume that the IP and electron affinity (EA) sectors are decoupled.^{280–283} For CC2,^{284,285} CC3,^{244,245,286–288} and CC4,^{239,289–291} diagonalization in the $(N - 1)$ -electron sector of the Fock space is not available yet. Hence, it has been carried out in the N -electron sector of the Fock space^{36,37,292–296} with an additional very diffuse (or bath) orbital with zero energy to obtain ionization and satellite energies. Therefore, at the CC2 level, the EOM space includes the one-hole-one-particle (1h1p) and the two-hole-two-particle (2h2p) configurations, while the three-hole-three-particle (3h3p) and four-hole-four-particle (4h4p) configurations are further added at the CC3 and CC4 levels, respectively. These two schemes produce identical IPs and satellite energies but, for a given level of theory, the diagonalization in the N -electron sector is more computationally demanding due to the larger size of the EOM space (see Ref. 297 for more details). In each scheme, the desired states have been obtained thanks to

the root-following Davidson algorithm implemented in CFOUR. The initial vectors were built using the dominant configurations of the SCI vectors.

The Δ CCSD(T) calculations have been performed with GAUSSIAN16.²⁶³ These calculations are based on a closed-shell restricted HF reference and an open-shell unrestricted HF reference for the neutral and cationic species, respectively.¹⁴⁹

C. Green’s function calculations

Many-body Green’s function calculations have been carried out with the open-source software QUACK.²⁹⁸ In the following, we use the acronyms G_0W_0 , $G_0F(2)$, and G_0T_0 to refer to the one-shot schemes where one relies on the GW , second-Born, and T -matrix self-energies, respectively. Each approximated scheme considered in this work (G_0W_0 , $qsGW$, $G_0F(2)$, and G_0T_0) relies on HF quantities as starting point. We refer the reader to Refs. 81 and 150 for additional details about the theory and implementation of these methods. The infinitesimal broadening parameter η is set to $0.001 E_h$ for all calculations. It is worth mentioning that we do not linearize the quasiparticle equation to obtain the quasiparticle energies. The $qsGW$ calculations are performed with the regularized scheme based on the similarity renormalization group approach, as described in Ref. 113. A flow parameter of $s = 500$ is employed. All (occupied and virtual) orbitals are corrected. The spectral weight of each quasiparticle solution is reported in Supporting Information. Compared to the EOM-CC formalism discussed in Sec. II B, it is important to mention that, in the Green’s function framework, the IP and EA sectors [*i.e.* the 1h and one-particle (1p) configurations] are actually coupled,^{150,282,299} effectively creating higher-order diagrams.^{82,299}

III. RESULTS AND DISCUSSION

The present section is partitioned into subsections, each dedicated to a distinct group of related molecules. Within these subsections, we focus our attention mainly on the satellite states while IPs are addressed in Sec. III G.

Each state considered in this work is reported alongside its symmetry label, *e.g.* 1^2B_1 for the principal IP of water. Furthermore, the main orbitals involved in the ionization process are specified. For example, the N -electron ground state of water has the following dominant configuration $(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2$, while the configuration of the $(N - 1)$ -electron ground state is $(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^1$. Hence, we denote the principal IP as $(1b_1)^{-1}$ to indicate that an electron has been ionized from the $1b_1$ orbital. The lowest satellite of water, *i.e.* the 2^2B_1 state of configuration $(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^1(1b_1)^1(4a_1)^1$, is labeled as $(3a_1)^{-1}(1b_1)^{-1}(4a_1)^1$ to signify that one electron was detached from the orbital $1b_1$ and $3a_1$, one of them being

FIG. 1. Gaussian fit of the experimental ionization spectrum of water in gas phase measured by Ning and coworkers. The fitting parameters can be found in Ref. 204. The red peak at 27.1 eV has been magnified by a factor 10.

subsequently promoted to the virtual orbital $4a_1$ and the other ionized. In some cases, additional valence complete-active-space CI calculations have been performed using MOLPRO to determine the symmetry of the FCI states.³⁰⁰

A. 10-electron molecules: Ne, HF, H₂O, NH₃, and CH₄

The water molecule has been extensively studied experimentally using photoionization and electron impact spectroscopy.^{204,306,307} For example, a high-resolution spectrum of liquid water is crucial as a first step for understanding the photoelectron spectra of aqueous phases.^{5,6} On the other hand, its gas-phase ionization spectrum is now well understood. The experimental ionization spectrum of water is plotted in Fig. 1, serving as a representative example to illustrate the following discussion. The first three sharp peaks at 12.6, 14.8, and 18.7 eV are associated with electron detachments from the three outer-valence orbitals, $1b_1$, $3a_1$, and $1b_2$, respectively.²⁰⁴ Then, a broader yet intense peak corresponding to the fourth ionization, $(2a_1)^{-1}$, is found at 32.4 eV surrounded by several close-lying satellite peaks. Additionally, there is a smaller broad satellite peak at 27.1 eV (magnified red peak in Fig. 1).

Table I gathers the FCI reference values corresponding to the three lowest satellites identified in our study. The first two, which are of 2B_1 and 2A_1 symmetries, lie close to each other around 27.1 eV. The third satellite is of 2B_1 symmetry and is found at slightly higher energy, approximately 29 eV. The ordering and the absolute energies of the three satellites align well with previous SAC-CI results reported by Ning *et al.*²⁰⁴ In addition, they showed that, at the ADC(3) level, the energy of the 2^2A_1 state is overestimated by approximately 2.7 eV while the 2^2B_1 and 3^2B_1 states are missing. It is also worth noting that early CI and Green's function studies had qualitatively predicted the 2^2A_1 satellite.^{12,187} Finally, we do

not consider the broad peak at 32.4 eV here because it is technically out of reach for our current SCI implementation. However, it has been studied by Mejuto-Zaera and coworkers who have shown that vertex corrections are required to correctly describe this complex part of the spectrum where strong many-body effects are at play.¹³

For the three satellites of water, CCSDTQ is in near-perfect agreement with FCI in all basis sets with errors inferior to 0.03 eV. CC4 is slightly worse than CCSDTQ but is still an excellent approximation given its lower computational cost and its approximate treatment of quadruples. The CCSDT satellite energies are overestimated by approximately 0.5 eV, while CC3 appears to struggle for this system. Indeed, the CC3 energies are badly underestimated with errors up to 1.5 eV, and the ordering of the first two satellites is wrongly predicted.³⁰⁸ Finally, CCSD and CC2 are not considered for satellites as their poor performance (wrong by several eV) makes the assignment of these states extremely challenging.

The remainder of this section is concerned with four molecules isoelectronic to water, namely CH₄, NH₃, HF, and Ne. For each of these molecules, Table I provides FCI reference values for the IPs corresponding to the two outermost valence orbitals. In addition, two satellite energies are reported for hydrogen fluoride and ammonia while one satellite is presented for methane and neon. Experimental values for the IPs of these four molecules have been measured multiple times and are reported in Table I.^{4,7,189,191,192,301,303,309–311}

Yenchu and coworkers measured the inner-valence photoelectron spectrum of HF. It displays a well-defined peak around 33 eV which appears in close agreement with the FCI energies for the $2^2\Sigma^+$ state.³¹¹ In addition, a doubly-degenerate satellite of $^2\Delta$ symmetry has also been computed. In the various NH₃ ionization spectra reported in the literature, there is no satellite peak around 24 eV which may correspond to the 2^2A_1 and 2^2E FCI states.^{189,201,301} Nevertheless, the FCI energies align well with the SAC-CI energies of Ishida and coworkers who predicted that these two satellite states have very low intensity.²⁰¹ The first satellite observed in the inner-valence region of the photoionization spectrum of CH₄ is a very weak and broad peak at 29.2 eV.³⁰² This peak is also measured at 28.56 eV using electron momentum spectroscopy experiments.¹⁹² The energy of the first satellite calculated at the FCI level, and associated with the $(2t_2)^{-2}(3a_1)^{-1}$ process, compares well with the experimental data. Finally, the lowest-energy satellite state of neon is also reported along with the corresponding experimental value measured by Joshi and co-workers.³⁰⁵ It is worth noting that CC3 behaves similarly in Ne, HF and H₂O, yet it appears to be a much better approximation for the satellite states of NH₃ and CH₄.

Among the 12 IPs computed for this series of molecules, 11 of them have a weight larger than 0.85 on the 1h dominant configuration (in the aug-cc-pVDZ basis set). Only the 3^2A_1 state of ammonia has a quite smaller weight (0.58) on the corresponding 1h determinant. This

TABLE I. Valence ionizations and satellite transition energies (in eV) of the 10-electron series for various methods and basis sets. AVXZ stands for aug-cc-pVXZ (where X = D, T, and Q). Selected experimental values are also reported.

exemplifies the breakdown of the orbital picture in the inner-valence ionization spectrum,^{12,169–181} which signature is a significant weight on both 1h and 2h1p configurations, hence preventing us from assigning the solution as a clear IP or satellite. The performance of the various approximations for IPs will be statistically gauged in Sec. III G.

B. Satellite in Green’s functions methods

Thus far, we have exclusively assessed the performance of different rungs of the CC hierarchy. Although shake-up transition energies can also be computed within the Green’s function framework, the task is notably more challenging, especially when compared to the more straightforward nature of IP-EOM-CC. This complexity arises from the fact that satellites, existing as non-linear solutions of the quasiparticle equation,⁷⁹ prove much more difficult to converge using Newton-Raphson algorithms than the quasiparticle solutions, which are representative of typical IPs. Fortunately, an alternative and equivalent pathway exists where one solves a larger linear eigenvalue problem instead of solving the non-linear quasiparticle equation.^{82,125,150,283,312–316} In such a case, satellites are obtained as higher-energy roots via diagonalization of the so-called “upfolded” matrix built in the basis of the 2h1p and two-particle-one-hole (2p1h) configurations in addition to the 1h and 1p configurations.

The satellite energies of H₂O and NH₃ computed with G₀W₀, G₀F(2), and G₀T₀ are presented in Table II. qsGW is not considered here as its static approximation naturally discards all the satellite solutions. The third column shows the diagonal elements of the upfolded matrix associated with the 2h1p configurations, while the fourth column displays the associated eigenvalues. One can immediately

observe that the eigenvalues do not improve upon the diagonal elements. This is due to the lack of higher-order (such as 3h2p) configurations that are essential to correlate satellites. This parallels the description of double excitations which require at least triple excitations (*i.e.* 3h3p configurations) in addition to the 2h2p configurations to correlate doubly-excited states.^{9–11} Regarding the two satellites of ammonia, the *T*-matrix zeroth-order elements are utterly inaccurate. This discrepancy arises because, at the *T*-matrix level, satellite energies are described as the sum of a Koopmans’ electron attachment energy (1p configuration) and a double electron detachment energy [two-hole (2h) configuration] stemming from the particle-particle random-phase approximation.^{150,317–320} On the other hand, G₀W₀ and G₀F(2) offer decent estimates of these satellite energies. The difference in performance of G₀T₀ and G₀W₀ can be understood in terms of the scattering channels that are accounted for in each of these approximations. We refer the interested reader to Ref. 147 and references therein.

The remaining three rows of Table II contain the energies corresponding to the three satellites of water discussed previously. The 2 ²A₁ state is the easiest to identify as its 2h1p dominant configuration clearly corresponds to the (1b₁)^{−2}(4a₁)¹ process. The eigenvectors associated with the 2 ²B₁ and 3 ²B₁ states, which correspond to the (3a₁)^{−1}(1b₁)^{−1}(4a₁)¹ and (1b₁)^{−1}(3a₁)^{−1}(4a₁)¹ processes respectively, are nearly degenerate and highly entangled. This is thus harder, if not impossible, to assign these states.

Because of these assignment problems, the G₀W₀, G₀F(2), and G₀T₀ satellite energies have not been computed for the other molecules considered in this study. To alleviate this issue, there is a notable appeal for a self-energy approximation including vertex corrections capable of effectively addressing satellite states. As mentioned previously, Green’s-function-based methods such as the 2ph-TDA¹⁷¹ and ADC(3)^{180,321,322} (first named extended 2ph-TDA¹⁷⁹) have shown success in qualitatively modeling the inner-valence region of experimental spectra.^{12,169–179,181,323} Sokolov’s recent multi-reference ADC(2) scheme³²⁴ is also a promising avenue. In particular, it has shown potential in describing the satellites of the carbon dimer (see below).^{234,235} While a detailed quantitative analysis of these approaches on the present benchmark set would be interesting, it lies beyond the scope of this study.

C. 14-electron molecules: N₂, CO, and BF

The nitrogen and carbon monoxide molecules have been extensively studied both experimentally^{326–332} and theoretically.^{39,169,180,182,183,185,197,333–335} Their ionization spectra are similar as they exhibit three sharp and intense peaks, corresponding to Koopmans’ states, below 20 eV. Their respective fourth IP, corresponding to electron detachment from the orbital 2σ_g for N₂ and 3σ

TABLE III. Valence ionizations and satellite transition energies (in eV) of the 14-electron series for various methods and basis sets. AVXZ stands for aug-cc-pVXZ (where X = D, T, and Q). Selected experimental values are also reported.

for CO, lies above 30 eV. Several peaks can be found below these ionizations, *i.e.* between 20 and 30 eV.^{326,329,330} These correspond to satellite states associated with the three outer-valence orbitals. Note that Schirmer *et*

al. have shown (using the 2ph-TDA method¹⁷¹) that the quasiparticle approximation breaks down in the region of the fourth ionizations of CO and N₂.^{169,180} However, as shown below, the peaks between 20 and 30 eV have a

well-defined satellite character.

Baltzer *et al.* produced, using He(II) photoelectron spectroscopy, accurate experimental values for the outer-valence IPs (see Table III) and the first satellite peaks of N₂.³²⁷ In particular, they reported a value of 25.514 eV for an intense satellite peak, as well as 24.788 eV for a very weak peak. These peaks were assigned $^2\Sigma_u^+$ and $^2\Pi_g$ symmetry, respectively, based on CI calculations. Note that the $^2\Pi_g$ satellite peak is more intense when measured by resonance Auger spectroscopy.³²⁶ We report FCI values for both satellites as well as a slightly higher third one with $^2\Sigma_u^-$ symmetry. This latter state is not observed experimentally but plays an important role nonetheless as it is involved in the dissociation pathways between the $^2\Sigma_u^+$ and $^4\Pi_u$ states.³³³

Similar to its isoelectronic N₂ molecule, CO exhibits shake-up peaks between the $(4\sigma)^{-1}$ and $(3\sigma)^{-1}$ ionizations. Using monochromatized X-ray excited photoelectron spectroscopy, Svensson *et al.* observed an intense $^2\Sigma^+$ satellite peak with energy 23.7 eV as well as a weak $^2\Pi$ satellite at 22.7 eV.³²⁶ This is in agreement with older He(II) photoelectron spectroscopy experiments done by Asbrink and coworkers.³³⁰ FCI values for both satellites, as well as for the higher-energy $1^2\Delta$ state, are reported in Table II.

The performance of CC schemes for these six satellites is similar to what we have observed for the 10-electron series. Yet, it is interesting to note that CCSDTQ seems to struggle slightly more with the $2^2\Pi$ satellite of CO and the $1^2\Pi_g$ and $1^2\Sigma_u^-$ states of N₂.

The boron fluoride molecule is isoelectronic to CO and N₂ but its ionization spectrum is much harder to obtain experimentally because BF is a quite non-volatile compound, meaning that the measurements have to be done at high temperatures.³²⁵ Yet, Hildenbrand and coworkers managed to measure its principal IP using electron impact spectroscopic and they reported a value of 11.06 eV. The $1^2\Sigma^+$ FCI state is in good agreement with this value. Table II also displays two additional IPs and one satellite. The order of the $^2\Pi$ states in BF is reversed with respect to its isoelectronic species: the $(5\sigma)^{-2}(2\pi)^1$ satellite state has a lower energy than the $(1\pi)^{-1}$ ionization. In this case, CCSDTQ accurately describes the satellite of Π symmetry.

D. 12-electron molecules: LiF, BeO, BN, and C₂

We now direct our attention toward the 12-electron isoelectronic molecules: LiF, BeO, BN, and C₂. These four molecules are quite challenging for theoretical methods as, except for LiF, their ground states have a strong multi-reference character.^{337–344} For example, BN and BeO are among the eight molecules of the GW100 set having multiple solution issues at the GW level.^{24,25} (C₂ is not considered in the GW100 set but would certainly fall in the same category.) Another noteworthy observation about these molecules is that their lowest unoccupied

molecular orbital has a negative energy, which means that their respective anions are stable.

LiF is a relatively non-volatile molecule, and as a result, experimental data became accessible during the second phase of the development of ultraviolet photoelectron spectroscopy.³³⁶ In addition, lithium fluoride vapor is not solely composed of monomers but also includes dimers, trimers, or even tetramers, posing challenges for more precise measurements of the Koopmans states of LiF. Berkowitz *et al.* measured the first two IPs using He(I) photoelectron spectroscopy: 11.50, 11.67, and 11.94 eV for the $1^2\Pi_{3/2,3/2}$, $1^2\Pi_{3/2,1/2}$, and $1^2\Sigma^+$ states, respectively. In our study, the spin-orbit coupling is not accounted for. Therefore, we report a single value for the $1^2\Pi$ state, while experimentally two distinct ionization energies are measured.

To the best of our knowledge, no gas phase experimental values are available for the three remaining species (see Ref. 345 for a study in solid phase). Nonetheless, they are an interesting playground for theoretical methods due to their multi-reference character. We start by discussing BeO as it has the less pronounced multi-reference character out of these three molecules. Table IV displays the excitation energies of the two lowest Koopmans states and the first two satellites. These four states have the same dominant configurations and ordering as the ones of lithium fluoride. However, the satellite states of BeO are much lower in energy than those of LiF. The $2^2\Pi$ state of BeO is interesting as it exhibits the largest error of this benchmark set at the CCSDTQ level. At the CC4 level, the $2^2\Pi$ and $1^2\Sigma^-$ states are drastically underestimated. This is also the case for the two satellite states of LiF, these four states having, by far, the largest CC4 errors of this benchmark set. They are also hugely underestimated at the CC3 level and, as for CC2 and CCSD, we have not reported these energies as they are not meaningful. Unfortunately, at this stage, we have no clear explanation for the failure of CC3 and CC4 in LiF and BeO.

BN and C₂ have the strongest multi-reference character among these four molecules.³⁴⁴ The ordering of their state differs from the one of LiF and BeO as their lowest satellite states are below their second IP. Furthermore, the ordering of the satellites is also different than the two previous molecules. The first satellite of boron nitride has the same dominant configuration as in the latter two molecules but the second satellite is of $1^2\Delta$ symmetry with a $(1\pi)^{-2}(5\sigma)^1$ dominant process. This satellite is also found in C₂ but even lower in the energy spectrum as the $1^2\Delta_g$ state is the lowest-energy satellite of the carbon dimer. Table IV reports two additional FCI satellite transition energies of C₂. Note that the satellite transition energies of BeO, BN, and C₂ are the lowest of the present set. The three satellite states of the carbon dimer have already been studied by Chatterjee and Sokolov.^{234,235} In particular, they have shown that ADC(3) performs poorly and does not even predict enough satellite states. On the other hand, their extension of ADC(2) using a multi-determinantal reference³²⁴ can predict each state

TABLE IV. Valence ionizations and satellite transition energies (in eV) of the 12-electron series for various methods and basis sets. AVXZ stands for aug-cc-pVXZ (where X = D, T, and Q). Selected experimental values are also reported.

row analog in some of the molecules discussed above. These molecules with more diffuse density have their ionization shifted towards zero with respect to their second-row counterparts (see Tables V, VI, and VII). Consequently, the breakdown of the orbital picture occurs at lower energy,¹⁷² which has been of interest historically as it allowed measuring spectra featuring such intricate structures more easily.

The first molecule considered in this subsection is carbon sulfide. In 1972, two independent studies measured

its photoelectron spectrum up to 20 eV.^{348,349} One can clearly distinguish four well-defined peaks in this energy range. While the assignment of the two lowest peaks is straightforward, *i.e.* IPs associated with the two outermost orbitals, the interpretation of the other two remained elusive for several years. Thanks to theoretical studies performed several years later, it became clear that the third peak is due to a multi-particle process while the fourth one is associated with an electron detachment from the orbital 6σ .^{172,234,235,308} Note that, as explained by

Schirmer *et al.*,¹⁷² one has to be particularly careful when labeling the third peak as a satellite because its FCI vector has a coefficient of 0.49 on the $1h$ configuration $(6\sigma)^{-1}$ and of 0.40 on the $2h1p$ configuration $(2\pi)^{-1}(7\sigma)^{-1}(3\pi)^1$ (in $6-31+G^*$ basis set). This is yet another example of a strong configuration mixing.

Despite this, the $2^2\Sigma^+$ state is classified as a satellite in Table V. Indeed, higher in energy there is another FCI solution of $2^2\Sigma^+$ symmetry with an even larger weight, 0.63, on the $1h$ determinant $(6\sigma)^{-1}$ and coefficients smaller than 0.31 on the $2h1p$ determinants. In addition, the third peak has a pronounced vibrational structure while the fourth peak is sharp like the $(7\sigma)^{-1}$ one.³⁴⁹ This is why the higher $2^2\Sigma^+$ state is classified as the third single ionization in Table V. Two other satellite states, $3^2\Sigma^+$ and $1^2\Delta$, that are not visible on the experimental spectrum, are reported in Table V.

Next, we consider lithium chloride and compare it with its second-row analog, lithium fluoride. The experimental challenges outlined earlier for LiF are similar for LiCl. Experimental values have first been reported independently by two groups in 1979,^{336,350} and revised values, measured by He(I) spectroscopy, have been published recently,³⁴⁶ and are reported in Table V. The FCI results predict two close-lying satellites around 20 eV. Unfortunately, the experimental studies mentioned above do not probe this energy range. The ADC(3) calculations of Tomasello *et al.* also predict two satellite lines around 21.5 eV.³⁵¹

Finally, we examine the 18-electron isoelectronic hydrides as analogs to the 10-electron series discussed in Subsec. III A. Historically, it was quickly realized that the satellite structure of H_2S is significantly more complex than the one of H_2O .¹⁷⁴ This intricate structure can be observed in the electron momentum spectrum of French *et al.*³⁵² They recorded a first very weak satellite at 19.63 eV which is in agreement with earlier measurements³⁵³ as well as photoelectron spectrum measured using synchrotron radiation.³⁵⁴ Several years later, extensive SAC-CI results have been reported and show qualitative agreement with experiments.²⁰⁰ (See also earlier calculations from Refs. 193 and 195.) However, the FCI results (see Table VII) exhibit some significant difference with the SAC-CI results of Ehara *et al.* because the 2^2A_1 satellite has a lower energy than the 2^2B_2 state. In addition, the FCI transition energy associated with the 2^2B_1 state is 2 eV lower than the one computed in Ref. 200. The 2^2A_1 state is known to be the one observed at 19.63 eV in Ref. 352 and is sometimes referred to as a shake-down state as it “borrows” intensity from the higher-lying $(4a_1)^{-1}$ ionization.^{200,354,355} Our FCI estimate for this state is 18.745 eV while the SAC-CI energy of Ehara and collaborators is 20.00 eV.²⁰⁰ In this specific scenario, calculating the adiabatic transition energy related to this state would undoubtedly provide a more faithful comparison with the experimental result.

For PH_3 , there is one satellite of symmetry E that is analog to the two 2^2E state of NH_3 . However, in the case of phosphine, there is no analog for the 2^2A_1 satellite of

ammonia. This is in agreement with the SAC-CI results of Ishida *et al.* who also found a single satellite below the $(4a_1)^{-1}$ ionization threshold.²⁰¹

Two FCI states, with symmetry $2^2\Sigma^+$ and $2^2\Delta$, are reported for HCl. These states are analog to the HF satellites reported in Table I although they have significantly lower energies in HCl. The satellite structure between 20 eV and the $(4\sigma)^{-1}$ ionization around 26 eV is notably intricate.³⁵⁶ Additionally, this structure is characterized by weak signals and some of its features were even not observed in previous studies performed at a lower level of theory.^{357–359} The assignment of the various peaks in this energy range is beyond the scope of this work. Yet, one can mention that the first FCI satellite is in qualitative agreement with the first satellite peak measured by synchrotron radiation spectroscopy at 21.57 eV.³⁵⁶

The lowest-energy satellite of argon, which is the analog of the 2^2P satellite state of neon, is also reported. This satellite has been observed experimentally by Kikas *et al.* and is also reported in Table VII.³⁶⁰ The agreement of the FCI value with the experimental one is definitely not as good as for neon. On the other hand, CC3 provides an excellent approximation of the 2^2P satellite state of argon which is not the case for neon (see Table I).

F. Miscellaneous molecules: F_2 , CO_2 , CH_2O , and BH_3

In this last subset, a few miscellaneous molecules are considered. First, the F_2 molecule is of interest as it is isoelectronic to SiH_4 , PH_3 , H_2S , HCl and Ar . Due to the absence of third-row atoms in F_2 , Cederbaum *et al.* observed that there is no breakdown of the orbital picture, as observed in the 18-electron hydride series.¹⁷⁰ Three IPs and one satellite transition energy of fluorine are reported in Table V. As documented in Ref. 170, these four states have a clear dominant configuration in their corresponding FCI vectors. The $2^2\Sigma_g^+$ satellite is not observed in photoionization^{303,361} or in electron impact spectra.³⁴⁷ However, a satellite state with the same symmetry and similar energy has been computed using ADC(4) and multi-reference CI.³⁴⁷

Carbon dioxide and formaldehyde are two small organic molecules that have been widely studied both experimentally and theoretically. Experimental studies have shown that CO_2 first measurable satellite peak is around 22 eV,^{188,205,328,362} while four ionization peaks are observed below 20 eV. Tian’s experimental values for these IPs, measured by electron momentum spectroscopy, are reported alongside our FCI estimates in Table VIII.²⁰⁵ These IPs have already been computed at various levels of theory such as CI,¹⁸⁸ ADC,^{234,235,362} SAC-CI,^{194,205} CC,³⁵ and even FCI.^{234,235}

The spectrum of formaldehyde is slightly harder to interpret. The electron momentum spectrum displays a sharp peak at 10.9 eV as well as a broad band between 12 and 18 eV.¹⁹⁰ On the other hand, one can observe four different peaks below 17 eV in the corresponding photoion-

FIG. 2. Mean signed error (MSE) [upper panel] and mean absolute error (MAE) [lower panel] with respect to FCI of the various methods considered in this work. These errors are computed for the 58 IPs of this set in the aug-cc-pVTZ basis set.

ization spectra.^{177,363} These peaks clearly correspond to ionizations from the four outermost orbitals (see Table VIII) and have already been computed using both wave function and Green’s function methods.^{35,38,177,234,235,334} Hochlaf *et al.* also mention a very weak band around 18 eV assigned as a satellite of 2B_2 symmetry,³⁶³ which can also be observed in Ref. 177. This is in nice agreement with the 3 2B_2 FCI satellite state. There is an additional 2 2B_1 satellite state with slightly lower energy than the previous one.

Finally, a small boron hydride is considered as we have seen above that boron-containing molecules such as BN are quite challenging. To the best of our knowledge, experimental results on BH_3 are quite scarce but the principal IP has been measured using mass spectroscopy in the 60’s.^{364,365} These two research groups reported quite different values of 12.32 eV³⁶⁴ and 11.4 eV.³⁶⁵ The FCI values, presented in Table VIII, is closer to the first one, corroborating the findings of Tian *et al.*, who computed similar values using propagator-based methods as well as CCSD(T).³⁶⁶ Finally, two FCI satellite transition energies of BH_3 are reported in Table VIII.

G. Global statistics

Finally, after discussing each molecule individually, the statistics over the whole set are reported and discussed in this subsection. Figure 2 displays the mean sign error (MSE) and MAE of the various methods considered in this study with respect to the new FCI references.

TABLE VI. Mean absolute error (MAE), mean signed error (MSE), root mean square error (RMSE), standard deviation error (SDE), minimum and maximum errors (in eV) with respect to FCI of the various methods considered in this work. These descriptors are computed for the 58 IPs of this set in the aug-cc-pVTZ basis set. The Δ CCSD(T) statistical descriptors correspond only to the 23 principal IPs.

Methods	MAE	MSE	RMSE	SDE	Min	Max

These statistical errors have been computed for the 58 IPs in the aug-cc-pVTZ basis set. Several other statistical descriptors are also reported in Table VI.

The CC hierarchy (CCSD, CCSDT, and CCSDTQ) behaves as expected, *i.e.* being more and more accurate as the rank of the excitation is increased. Chemical accuracy (*i.e.*, error below 0.043 eV as represented by the horizontal green line in the lower panel Fig. 2) is reached at the CCSDT level. The least expensive CC2 method does not perform well for IPs as already observed previously.^{367–369} This has been attributed to the same underlying issue observed in CC2 for Rydberg³⁷⁰ and charge-transfer excited states.³⁷¹

Figure 2 also shows that CC3 and CC4 are good approximations, for IPs, of their respective parents, CCSDT and CCSDTQ. This could have been expected for CC3 as it is known to be a good approximation of CCSDT for Rydberg excited states.³⁷⁰ In addition, these four methods have very small MSEs and do not, on average, underestimate (as CC2) or overestimate (as CCSD) the IPs. Therefore, implementations of IP-EOM-CC3 and IP-EOM-CC4 would be valuable to lower the cost of the present implementation based on EE-EOM. CC3 and CC4 could be certainly employed as reference methods for larger molecular systems.^{239,291,372}

For the sake of completeness, we also report in Table VI the statistical descriptors for the propagator methods. However, their trends are now well-known.^{113,142,149,150} The G_0T_0 MAE is very close to the G_0W_0 one whereas the second-Born approximation exhibits significantly poorer performance.^{142,149,150} The self-consistent qsGW slightly mitigates the error compared to the one-shot GW version. It is also interesting to note that GF2 results are very close to those of CC2. This could have been expected as GF2 is equivalent to ADC(2)^{82,124,150} and the latter is closely related to the CC2 approximation.³⁷³

Finally, the principal IP of the 23 molecules considered

TABLE VII. Mean absolute error (MAE), mean signed error (MSE), root mean square error (RMSE), standard deviation error (SDE), minimum and maximum errors (in eV) with respect to FCI of the various methods considered in this work. These descriptors are computed for the 36 satellites of this set in the aug-cc-pVTZ basis set. The satellites of LiF and BeO have been excluded (see main text).

Methods	MAE	MSE	RMSE	SDE	Min	Max
CC3	0.787	0.143	0.936	0.937	-2.907	1.098
CCSDT	0.537	0.537	0.590	0.248	0.104	1.195
CC4	0.093	-0.001	0.134	0.136	-0.423	0.333
CCSDTQ	0.039	0.034	0.054	0.043	-0.030	0.143

so far have been computed at the $\Delta\text{CCSD(T)}$ in the aug-cc-pVTZ basis set (see [Supporting Information](#)). This method has been used as the reference for the *GW*100 dataset and it is interesting to benchmark it now that we have access to FCI references.^{25,61,149,374} The last line of Table VI reports the corresponding statistical descriptor. In particular, its MAE and MSE of 0.021 eV and 0.016 eV, respectively, show that the state-specific $\Delta\text{CCSD(T)}$ method can indeed be employed as a reference.

Figure 3 shows the distribution of the errors associated with the satellite transitions computed with CC methods including at least triple excitations, namely, CC3, CCSDT, CC4, and CCSDTQ. The corresponding statistical descriptors are reported in Table VII. The MAE of CCSDTQ is 0.039 eV, *i.e.* just below chemical accuracy, while CC4 and its approximate treatment of quadruples achieve a 0.093 eV MAE. Interestingly, while CC4 absolute errors are, on average, larger than CCSDTQ, its MSE is closer to zero. CC3 and CCSDT have MAEs of 0.787 eV and 0.537 eV, respectively, and once again CC3 has a lower MSE than its parent method (0.143 eV and 0.537 eV). Hence, methods accounting for triple excitations, even fully, should be used with care for satellites. It is also interesting to note that these MAEs align very well with those computed for double excitations, as reported in Ref. 10.

IV. CONCLUSION

We have reported 42 FCI satellite transition energies computed in 23 small molecules. These energies have been calculated with increasingly large basis sets ranging from Pople’s 6-31+G* to Dunning’s aug-cc-pVXZ (where $X = \text{D, T, and Q}$). In addition, 58 FCI reference values for outer- and inner-valence IPs of the same molecular set have been presented. This work is the tenth layer of reference values of the QUEST database^{23,237} and the first one to include charged excitations.

Various CC methods have been employed to compute IPs (CC2, CCSD, CC3, CCSDT, CC4, and CCSDTQ) and satellite transition energies (CC3, CCSDT, CC4, and

CCSDTQ), and their performances have been assessed using the FCI reference values. It has been shown that CC3 and CC4 are faithful approximations of CCSDT and CCSDTQ for IPs, respectively, while the CC2 approximate treatment of double excitations induces large errors with respect to CCSD. For the satellites, our study reveals that chemical accuracy is reached only at the CCSDTQ level, highlighting the intricate and complex correlation effects involved in such states and their overall challenging nature for computational methods.

The performance of various propagator methods (G_0W_0 , $G_0F(2)$, G_0T_0 , and qsGW) have also been gauged. The poor performance of these methods for satellite transition energies has been discussed in detail. These results call for the development of new methods capable of describing such states. For example, considering explicitly the three-body Green’s function in order to describe IPs and satellites on an equal footing could offer significant advantages.^{376,377} Studying the convergence of the ADC hierarchy using these new benchmark values is another possible outlook. Finally, assessing methods designed in the condensed matter community, such as the cumulant Green’s function, on these small molecular systems would certainly be interesting. Work along this line is presently underway.³⁷⁸

One obvious perspective that needs to be addressed is the extension to transition intensities, which are of crucial importance for direct comparisons with experimental spectra. An approximate electronic structure method should not only aim to accurately describe the excited-state energy but also the transition intensities associated with it. Within the present SCI formalism, computing intensities is not straightforward but this is feasible, as demonstrated in Refs. 13, 379, and 380, and is planned for future investigation.

FIG. 3. Distribution of the errors with respect to FCI of the various methods considered in this work. These errors are computed for the 36 satellites of this set in the aug-cc-pVTZ basis set. The satellites of LiF and BeO have been excluded (see main text). Note the different scale of the horizontal axis in the leftmost plot.

as the FCI incertitudes and the spectral weight associated with the G_0W_0 , $G_0F(2)$, and G_0T_0 quasiparticle energies.
