Abstract

We present the design and implementation of the Small Scale Reflection proof methodology and tactic language (*a.k.a.* SSR) for the Lean 4 proof assistant. Like its Coq predecessor **SSReflect**, our Lean 4 implementation, dubbed **LeanSSR**, provides powerful rewriting principles and means for effective management of hypotheses in the proof context. Unlike **SSReflect** for Coq, **LeanSSR** does not require explicit switching between the *logical* and *symbolic* representation of a goal, allowing for even more concise proof scripts that seamlessly combine deduction steps with proofs by computation.

In this paper, we first provide a gentle introduction to the principles of structuring mechanised proofs using **LeanSSR**. Next, we show how the native support for metaprogramming in Lean 4 makes it possible to develop **LeanSSR** entirely within the proof assistant, greatly improving the overall experience of both tactic implementers and proof engineers. Finally, we demonstrate the utility of **LeanSSR** by conducting two case studies: (a) porting a collection of Coq lemmas about sequences from the widely used Mathematical Components library and (b) reimplementing proofs in the finite set library of Lean’s `mathlib4`. Both case studies show significant reduction in proof sizes.

1 Introduction

Small Scale Reflection (SSR) is a methodology for structuring deductive machine-assisted proofs that promotes the pervasive use of *computable symbolic* representations of data properties, in addition to their more conventional logical definitions in the form of inductive relations. Small scale reflection emerged from the prominent effort to mechanise the proof of the Four Colour Theorem in the Coq proof assistant [9], in which the large number of cases to be discharged posed a significant scalability challenge for a traditional proof style based on tactics that operate directly with the logical representation of a goal. Support for small scale reflection in Coq has later been implemented in the form of the **SSReflect** plugin, which provides a concise tactic language, and its associated library of lemmas [11], becoming an indispensable tool for the working Coq user. **SSReflect** has been employed in many projects, including mechanisations of the foundations of group theory [10], measure theory [2], information theory [3], 3D geometry [1], programming language semantics [30], as well as proving the correctness of heap-manipulating, concurrent and distributed programs [20, 23, 26, 27], and probabilistic data structures [12]. Two **SSReflect** tutorials [18, 25] are currently recommended amongst the basic learning materials for Coq [6].

Lean 4 is a relatively new proof assistant and dependently typed programming language [7].¹ Like Coq, Lean is based on the Calculus of Constructions with inductive types and is geared towards interactive proofs, coming with extensive support for metaprogramming aimed at simplifying custom proof automation and code generation. Unlike Coq, Lean assumes axioms of classical logic, such as the law of excluded middle. Very much in the spirit of the SSR philosophy of *reflecting* proofs about decidable propositions into Boolean-returning *computations*, Lean encourages the use of such propositions (implemented

¹ In the rest of the paper, we will refer to the latest version 4 of the framework simply as Lean.

as an instance of the `Decidable` type class) *as if they were* Boolean expressions, going as far as providing a program-level `if-then-else` operator that performs conditioning on an instance of a decidable proposition. Given this similarity of approaches, it was only natural for us to try to bring the familiar SSR tactic language to Lean, as an alternative to Lean’s descriptive but verbose idiomatic approach to proof construction. Our secondary motivation was to put Lean’s metaprogramming to the test, implementing SSR entirely within the proof assistant, in contrast with `SSReflect`, which is implemented as a Coq plugin in OCaml.

In this paper, we present `LeanSSR`, a proof scripting language that faithfully replicates the `SSReflect` experience in Lean, yet provides *substantially better* proof ergonomics, thanks to Lean’s distinctive features, improving on its Coq predecessor in the following three aspects:

1. *Usability*: Compared to Coq/`SSReflect`, which only shows the proof context between complete series of chained tactic applications, `LeanSSR` provides a more fine-grained access to the proof state, displaying its changes after executing each “atomic” step—a feature made possible by Lean’s mechanism of proof state annotations.
2. *Expressivity*: Unlike `SSReflect` for Coq, `LeanSSR` does not require the user to explicitly switch between representation of facts as logical propositions or as symbolic expressions to advance the proof. In particular, this automation makes it possible to unify simplifications via computation and via equality-based rewriting, resulting in very concise proof scripts.
3. *Extensibility*: Since `LeanSSR` is *lightweight*, *i.e.*, it is implemented entirely in Lean using its metaprogramming facilities, it can be easily enhanced with additional tactics and proof automation machineries specific to a particular project that uses it.

In the rest of the paper, we showcase `LeanSSR`, substantiating the three claims above.

Contributions and Outline. In this work, we make the following contributions:

- An implementation of `LeanSSR`, an `SSReflect`-style tactic language for Lean.²
- A tutorial on using `LeanSSR` following a series of characteristic proof examples (Sec. 2).
- A detailed overview of Lean metaprogramming features that we consider essential for implementing `LeanSSR` and the effect of those features on the end-user experience (Sec. 3).
- Two case studies demonstrating `LeanSSR`’s utility for proof migration and evolution: (a) porting a collection of Coq lemmas about finite sequences from the MathComp library [18] to Lean and (b) reimplementing proofs from the finite set library of Lean’s `mathlib4` in `LeanSSR` (Sec. 4). While proof sizes reduce in both cases, we also comment on our overall better mechanisation experience, compared to refactoring original proofs in both Coq and Lean—thanks to the improved usability aspect highlighted above.

2 LeanSSR in Action

In this section we give a tutorial on the main elements of the `LeanSSR` proof language. We do not expect the reader to be familiar with the standard Lean tactics. This section will also be informative for the readers familiar with `SSReflect` for Coq due to the improvements `LeanSSR` makes over `SSReflect` in terms of usability (Sec. 2.4) and expressivity (Sec. 2.6).

2.1 Managing the Context and the Goal in Backward Proofs

As customary for interactive proof assistants based on higher-order logic, Lean represents the proof state as a logical *sequent*, as depicted in Fig. 1.

² The snapshot of `LeanSSR` development accompanying this submission is available online [8].

The proof *goal* is the logical statement below the horizontal line; above the line is the *local context* of the sequent, a set of constants c_i and facts (*i.e.*, hypotheses) F_k . The goal statement itself can be decomposed into (a) *goal context*: quantified variables $x_l : T_l$ and assumptions P_n , and (b) the *conclusion* statement C . Both local and goal contexts capture the bound variables (term-level or hypotheses) of the overall proof term to be constructed, with the only difference being the explicit names of the variables in the local context. Lean tactics, such as `apply`, operate directly on the goal's conclusion using variables from the local context referring to them by their names, while tactics such as `intro` and `revert` move variables/hypotheses between the local and the goal context. In practice, such “bookkeeping” of variables and hypotheses contributes most of the proof script burden; so, following SSReflect, LeanSSR provides tactics to streamline it.

$$\frac{\begin{array}{l} c_i : T_i \\ \dots \\ F_k : P_k \\ \dots \end{array}}{\forall x_l : T_l, \dots, P_n \rightarrow \dots \rightarrow C}$$

■ **Fig. 1.** Proof state as a sequent

Specifically, LeanSSR provides mechanisms to operate directly with the goal context, treating the goal as a *stack*, where the left-most variable or assumption is the top of the stack, and the conclusion is always at the bottom of the stack. By convention, most of LeanSSR tactics, operate with the top element of the goal stack. As an example, LeanSSR defines `sapply`, a variant of the standard Lean `apply` tactics (many LeanSSR tactics come with the prefix `s*` to distinguish them from their standard Lean counterparts) to simplify backward proofs [4, Chapter 3]. As Fig. 2a shows, `sapply` applies the first element on the goal stack (*i.e.*, the hypothesis of type α) to the rest of the stack (*i.e.*, the goal's conclusion α).

A typical proof in LeanSSR is done by moving variables and assumptions back and forth between the local context and the goal context, placing the terms to be used in a current proof step on top of the goal stack. Such proof context management is done via two complementary *tacticals*: `=>` and `:.`. The former one (`=>`) moves facts above the sequent line, whereas the latter one moves facts below, “pushing” them to the goal stack. Fig. 2b and 2c showcase the usage of `=>` and `:.`. The proof in Fig. 2b starts with `move=> hA ?`, where `move` essentially does nothing: its goal is to serve as a no-op tactic, to be followed by either `=>` or `:.`. What follows (`=> hA ?`) is an example of an *intro pattern* (more patterns will be shown below) that introduces the first two elements of the goal context, the first named `hA` and the second with an auto-generated name. To apply the introduced assumption `hA` we have to revert it back to the top of the proof context; the next line `move: hA` does exactly that.

Lean users might notice that `=>` and `:.` are similar to the standard `intro` and `revert` Lean tactics. Fig. 2c demonstrates the versatility of the LeanSSR tacticals when combined with different intro patterns. For instance, to swap the first two elements of the proof stack, Fig. 2c makes use of the `/[swap]` intro pattern. This will turn our goal to $(\alpha \rightarrow \beta) \rightarrow \alpha \rightarrow \beta$. Other useful SSReflect-inspired intro patterns include `*` for introducing *all* elements on the proof stack, `_` for discarding the first element on the proof stack, and `/[dup]` for duplicating the first element on the stack. Furthermore, as the purpose of LeanSSR tacticals is to “massage” the shape of the goal, they can be smoothly combined with other LeanSSR tactics

example: $\alpha \rightarrow \alpha :=$
by `sapply`

example: $\alpha \rightarrow \beta \rightarrow \alpha :=$
by `move=> hA ?`
`move: hA; sapply`

example: $\alpha \rightarrow (\alpha \rightarrow \beta) \rightarrow \beta :=$
by `move=> /[swap] hAiB`
`sapply: hAiB`

(a) Using `sapply` tactic (b) Basic LeanSSR proof script (c) A proof using `/[swap]` intro pattern

■ **Fig. 2.** LeanSSR proof scripts using the `sapply` tactic, `=>` and `:.` tacticals, and intro patterns.

that operate directly on the goal stack. In particular, Fig. 2c combines `sapply` with `:` (i.e., `sapply: hAiB`), with the effect of first pushing `hAiB :  $\alpha \rightarrow \beta$` to the goal stack and then executing the `sapply` tactic, discharging the goal similarly to the example from Fig. 2a.

2.2 Induction, Case Analysis, and Last-Mile Automation

LeanSSR combines the tacticals for the goal context management and intro patterns with tactics for proofs by induction and case analysis. In particular, LeanSSR introduces a variant of a standard `induction` tactic called `elim`, which expects no explicit arguments and simply applies the induction principle of the top element of the goal stack. As an example, consider the proof by induction in Fig. 3 of a simple property of natural addition and subtraction. As its first step, the proof generalises the two natural constants, `n` and `m` by pushing them onto the goal, making it $\forall n\ m, n \leq m \rightarrow m - n + n = m$; it is followed by an invocation of the induction principle for natural numbers on `n`, with `m` being universally quantified; all that expressed simply as `elim: n m`.

Unlike Lean’s `induction` tactic, `elim` does not introduce new variables and facts to the local context, leaving those universally quantified in the respective subgoals. In our example, using `elim` on a natural number introduces two subgoals, one for the base `zero` and one for the inductive step `succ`, with the latter featuring a predecessor variable and an inductive hypothesis. Naming variables in subgoals can be done using the *alternation separator* intro pattern of the form `[ ... | ... | ... ]` where each `...` section corresponds to introductions in a respective subgoal. We can, thus, revise our proof to be `elim: n m => [ | n IHn ]`, introducing the variable and the hypothesis step to the local context as `n` and `IHn`, respectively.

Let us focus on the second subgoal (i.e., the inductive step), which now looks as follows:

$$\forall m, n + 1 \leq m \rightarrow m - (n + 1) + (n + 1) = m \quad (1)$$

The proof of (1) can be finished by the case analysis on `m` using LeanSSR’s `sbase` tactic, which will generate two subgoals, one for `zero` and one for `succ`. The latter will introduce yet another universally-quantified variable, which can be suitably named and moved to the local context: `sbase=> [ | m' ]`. Such nested deconstructions of a goal’s top variable into cases are so frequent that LeanSSR overloads the alternation separator intro pattern to perform case analyses with simultaneous naming. Hence, we can now revise our proof to first perform top-level induction on `n` and then do case analysis on `m` in the resulting second subgoal via `elim: n m => [ | n IHn [ | m' ] ]`.

Having executed this proof script line, we are left with three subgoals to discharge:

$$\forall m : \mathbb{N}, 0 \leq m \rightarrow m - 0 + 0 = m \quad (2)$$

$$n + 1 \leq 0 \rightarrow 0 - (n + 1) + (n + 1) = 0 \quad (3)$$

$$(n + 1) \leq (m + 1) \rightarrow (m + 1) - (n + 1) + (n + 1) = (m + 1) \quad (4)$$

This would be a good time to make use of Lean’s famous automation to solve (2) and (3), and simplify (4). LeanSSR provides the following intro patterns for such “last-mile” automation:

- `/=` for simplification by evaluation (Lean’s `dsimp`) and `/==` for proofs by rewriting (`simp`)
- `//` for a lightweight automation combining Lean tactics `trivial` and `simp_all`
- `//=` abbreviating `dsimp=> //`, and `//==` abbreviating `simp=> //`

```
example (m n : Nat): n <= m ->
  m - n + n = m := by
  elim: n m=> [ | n IHn [ | m' ] ] //==
  move=> ?; srw -[2] (IHn m') //
```

■ Fig. 3. A proof by mathematical induction

<pre> n : Nat ⊢ (∀ (m : Nat), n ≤ m → m - n + n = m) → ∀ (m : Nat), Nat.succ n ≤ m → m - Nat.succ n + Nat.succ n = m </pre>	<pre> n : Nat IHn : ∀ (m : Nat), n ≤ m → m - n + n = m ⊢ ∀ (m : Nat), Nat.succ n ≤ m → m - Nat.succ n + Nat.succ n = m </pre>
---	---

(a) The proof view before introducing IHn

(b) The proof view after introducing IHn

■ **Fig. 4.** Visual support for fine-grained proof state exploration with LeanSSR proof scripts.

In this case, using `//==` on all generated subgoals leaves us with only one obligation to prove:

$$n \leq m' \rightarrow m' - n + (n + 1) = (m' + 1) \quad (5)$$

2.3 Targeted Rewriting using Equality Hypotheses

The remaining goal (5) can be proven using the previously introduced induction hypothesis `IHn : ∀ (m : Nat), n ≤ m → m - n + n = m`. Intuitively, the proof can be completed by replacing the highlighted *second* occurrence of `m'` in (5) with `m' - n + n` using the right-hand side of the equality in `IHn`, and then finish the proof by the properties of linear arithmetic and reflexivity. This can be achieved by LeanSSR rewriting tactic `srw` allowing one to specify the term occurrence to be rewritten. The proof script in Fig. 3 ends with moving the inequality `n ≤ m'` to the local context via `move=>?`, followed by `srw -[2] (IHn m')` `//`, where `-` stands for the right-to-left rewrite direction and `[2]` denotes the specific occurrence of `m'`. Performing this rewrite generates the obligation `n ≤ m'`, which is discharged via `//`.

The `srw` tactic generalises Lean’s vanilla `rw`, allowing for constructions such as:

```
srw (drop_nth _ lt_i_m) //== -[1]h nth_index // -index_mem
```

that interleave rewrites with simplifications, resolving the appearing subgoals with `//`.

2.4 Fine-Grained Proof State Exploration and Error Highlighting

As our examples so far demonstrate, proofs in LeanSSR tend to be quite compact, thanks to the concise nature of the tactic language that chains multiple manipulations with the goal and the proof context into a single line of a proof script. The downside of this style is that proofs often become difficult to follow and refactor—a frequent complaint by newcomers to Coq/SSReflect who are familiar with the vanilla Coq proof mode. The problem of proof script understanding and maintenance in SSReflect is exacerbated by the fact that Coq can only display the proof context between *complete* series of chained tactic applications separated by periods. When a mistake is made in the middle of a line in an SSReflect proof script, one typically has to manually break the line into period-terminated parts, performing a binary search-style debugging. In addition to that, if a particular intro pattern cannot be applied in SSReflect, say we write `[| | m]` with three alternations instead of two in the proof of Fig. 3, Coq will report an error for the entire script line, further complicating the search for a fix.

LeanSSR overcomes these hurdles, providing an improved (compared to SSReflect) experience to the users, thereby substantiating the usability claim (1) from Sec. 1.

First, the better proof debugging is made possible by the powerful feature of Lean that allows the DSL designer to annotate each symbol in the tactic definition with the proof state before and after its execution. For instance, if the user puts the pointer in the text buffer with her proof script before the `IHn` token in Fig. 3, the goal display will be as in Fig. 4a, highlighting the upcoming change in the goal in red. For the pointer positioned right after `IHn`, the goal display shows the proof context as in Fig. 4b. Second, Lean provides a tunable mechanism for precise error highlighting, so if we write `[| | m]` with three alternations instead of two, only highlight the `[| | m]` part of the script will be marked as an error.

2.5 Forward Reasoning via Views

So-called *backward* proofs, in which a conclusion of a goal is gradually strengthened to be eventually discharged from the available hypotheses or axioms, are prevalent in interactive proofs. A very simple example of such a proof is given in Fig. 5, which proves the conclusion C using the reverse-order applications of the assumptions $B \rightarrow C$, $A \rightarrow B$, and, eventually, A .

That said, proof engineers trained in a tradition of purely mathematical proofs often prefer the complementary *forward* style, in which the assumptions are gradually weakened to eventually imply the conclusion [4, Chapter 4]. A typical forward proof in Lean follows the so-called *assume/have/show* pattern, which explicitly states the $\forall$ -quantified variables and hypotheses as parameters of the proof term (*assume*) and the proof is comprised of a number of established auxiliary facts (*have*) that make the derivation of the conclusion trivial (*show*). An example of such a forward proof in the conventional Lean notation is shown in Fig. 6.

LeanSSR offers an alternative way to construct forward proofs using the idea of *view intro patterns* or simply *views*, adopted from the original SSReflect [11]. The proof of the fact from Fig. 5 and 6 can be achieved in LeanSSR by the following single line:

```
by sby move=> AiB BiC /AiB/BiC
```

Ignoring `sby` for a moment, notice that the proof first moves the hypotheses $A \rightarrow B$ and $B \rightarrow C$ to the context. What follows is an application of $A \rightarrow B$ to the leading (*i.e.*, top) assumption of the goal A , which “switches” it to B , making the goal to be $B \rightarrow C$. The subsequent view `/BiC` switches the leading assumption from B to C . The remaining goal $C \rightarrow C$ can be discharged by `trivial` (or LeanSSR’s `//`). This is done by the `sby` tactical at the beginning of the line, which either completes the proof via `//` or fails. In fact, this makes the second view redundant, so the proof can be shortened to `by sby move=> AiB ? /AiB`.

2.6 Proofs by Computational Reflection

The LeanSSR demonstration in Sec. 2.1–2.5 was merely a build-up to the true essence of the framework: mechanised reasoning that features both *deduction* and *proof via computation* by manipulating with equivalent *logical* and *symbolic* representations of decidable facts.

As a motivating example showing how to unify both these proof styles in LeanSSR, consider the following simple proposition: *assuming n is even, $n + m$ is even if and only if m is even*. How should we express a decidable property, such as evenness? Proof assistants based on higher-order logic, such as Coq, Isabelle/HOL, and Lean provide two conceptual ways to do so: as a *predicate* (cf. Fig. 7a) and as a *function* (cf. Fig. 7b). The former style comes with an advantage of providing a richer knowledge when a property occurs in a goal’s *assumption*, *e.g.*, by assuming `even n` we can deduce that it’s either zero or another even number plus two. The latter comes with a set of reduction/rewrite principles, such as, `evenb n + 2 = evenb n`, which is advantageous for simplifying the *conclusion* of a goal.

One can indeed establish an equivalence between the definitions `even` and `evenb`, proving that $\forall n, \text{even } n \leftrightarrow (\text{evenb } n = \text{true})$. Such an equivalence, when expressed as an

```
example (A B C : Prop) :
  (A → B) → (B → C) → A → C :=
by intro AiB BiC Ha
   apply BiC
   apply AiB
   exact Ha
```

■ Fig. 5. A backward proof in vanilla Lean

```
example (A B C : Prop) :
  (A → B) → (B → C) → (A → C) :=
fun AiB BiC Ha =>
  have Hb : B := AiB Ha
  have Hc : C := BiC Hb
  show C from Hc
```

■ Fig. 6. A forward proof in vanilla Lean

```
inductive even : Nat → Prop
  where
  | ev0 : even 0
  | ev2 : ∀ n, even n → even (n + 2)
```

(a) Even numbers as a logical predicate

```
def evenb : Nat → Bool
  | 0    => true
  | 1    => false
  | n + 2 => evenb n
```

(b) Even numbers via a Boolean function

```
@[reflect] instance evenP n : Reflect (even n) (evenb n) := ...
#reflect even evenb

example n m : even n → even (m + n) = even m := by
  elim=> // n' _ <-
  srw -Nat.add_assoc /==
```

(c) A proof using reflection between the logical (`even`) and symbolic (`evenb`) definition of even numbers.■ **Fig. 7.** Two equivalent definitions of even numbers (top), and a proof by reflection (bottom).

instance of the `Decidable` type class in Lean, can be exploited by allowing the user to define computations that explicitly feature a predicate instead of its computable version, such as:

```
def even_indicator (n: Nat) : Nat := if even n then 1 else 0
```

This treatment of decidability also explains the somewhat frivolous phrasing of our proposition of interest in terms equality instead of bi-implication ($\leftrightarrow$) in the statement in Fig. 7c. To summarise, for `Decidable` properties, Lean aggressively promotes the logical definitions to be considered as “primary”, while the symbolic ones serving merely as helpers for defining computations and, occasionally, for simplifying goals in the proofs about equivalent predicates.

This is exactly where `LeanSSR` comes into play, making such simplifications transparent to the user. Consider the proof of the example in Fig. 7c. The first line initiates the induction on the `even n` premise, discharging the first trivial subgoal (for the case `ev0`), binding the first argument `n'` of the case `ev2`, ignoring the `even n'` assumption (via `_`), and performing the right-to-left rewrite using the induction hypothesis `even (m + n') = even m` in the conclusion (via the `<-` intro pattern), leaving us with the following goal to prove:

$$\text{even } (m + (n' + 2)) = \text{even } (m + n')$$

The remaining goal is not difficult to prove by using associativity of addition and showing that $\forall x, \text{even } (x + 2) = \text{even } x$. But also, this is an equality that we should have “for free”, as it can be derived from the last clause of the definition of `evenb` in Fig. 7b!

To account for scenarios like this one, `LeanSSR` provides a machinery that allows one to inherit reduction rules of a recursive (symbolic) boolean definition `b` to simplify instances of the equivalent logical proposition `P`. To achieve that, one must prove an instance of the `Reflect P b` predicate, which is essentially equivalent to proving $P \leftrightarrow (b = \text{true})$ (we postpone the details of the `Reflect` definition until Sec. 3) and register this equivalence using the pragma `#reflect P b`, which is exactly what is done by the first two lines of Fig. 7c. In this case, doing so will add three simplification rules for `even` into a database of rewrites used by simplification tactics such as `simp` and the corresponding `LeanSSR` patterns, *e.g.*, `/==`:

$$\text{even } 0 = \text{True} \quad \text{even } 1 = \text{False} \quad \forall n, \text{even } (n + 2) = \text{even } n$$

These equalities allow us to finish the proof by `/==`, rewriting `even` as if it were `evenb`.

`LeanSSR`’s `Reflect` type class is well integrated with the current Lean ecosystem. Once one has proven `Reflect P b`, the corresponding `Decidable` instance is automatically derived for `P`. Readers familiar with `SSReflect` for Coq could notice that a proof of the statement

```

variable {α : Type} [DecidableEq α]

def mask: List Bool → List α → List α
| b :: m, x :: s =>
  if b then x :: mask m s else mask m s
| _, _ => []

def subseq (s1 s2 : List α) : Prop :=
  ∃ m, length m = length s2 /\
    s1 = mask m s2

def subseqb: List α → List α → Bool
| [], _ :: _ => true
| s, [] => s = []
| s@(x :: s'), y :: r =>
  subseqb (if x = y then s' else s) r

```

```

1 #reflect subseq subseqb
2
3 def transitive (R: α → α → Prop) :=
4   ∀ x y z, R x y → R y z → R x z
5
6 example: transitive (@subseq α) := by
7   move=> ?? s ! [m2 _ ->] ! [m1 _ ->]
8   elim: s m1 m2=> [// | x s IHs1]
9   scase=> [// | [] m1 /= m2]
10  { -- m1's head is false
11    scase!: (IHs1 m1 m2)=> m sz_m ->
12    sby exists (false :: m) }
13  -- m1's head is true
14  scase: m2=> [! [] m2] // =
15  scase!: (IHs1 m1 m2)=> m sz_m ->
16  sby exists (false :: m)

```

(a) Two representations of the subsequence relation

(b) Proof that `subseq` is transitive

■ **Fig. 8.** A subsequence relation and the proof of its transitivity in LeanSSR.

from Fig. 7c in it would be more verbose, as it would require an *explicit* switching between the logical predicate and its symbolic counterpart in the conclusion by applying a special `Reflect`-lemma to the goal. This is not necessary in LeanSSR thanks to Lean’s ability to use the derived rewriting principles (e.g., the three above for `even`) directly on logical representations. We believe this example supports the expressivity claim (2) from Sec. 1.

2.7 Putting It All Together

We conclude this tutorial by showing how all the features of LeanSSR introduced in Sec. 2.1–2.6 work in tandem in a proof of an interesting property: transitivity of the subsequence relation on lists of elements with decidable equality. Fig. 8a presents two ways to define the relation. The first one is via a predicate and an auxiliary `mask` function. The `mask` function takes two lists: a list of Boolean values `m` and a list `s` of elements of some type α . For each element of `s`, `mask` removes it if an element in `m` at the same position is either `false` or not present (i.e., `m` is shorter than `s`). Then the representation of subsequence as a logical predicate states that `s1` is a subsequence of `s2`, if `mask m s2 = s1` for some mask `m`. The second definition is via a total recursive function `subseqb` returning a Boolean. This definition we checks that each element in the first list corresponds to some element in the second list using the decidable equality on the values of type α , whose existence is postulated in the first line of the listing. For the propositional and Boolean representations above, we can prove a `Reflect` instance (cf. Sec. 2.6), and transport reduction principles of `subseqb` to `subseq` by adding the `#reflect` pragma as at the line 1 of Fig. 8b.

Fig. 8b shows the entire transitivity proof. At line 7, it introduces a new intro pattern `! [...]`, which is an advanced version of the case analysis `[...]`: not only does it destruct the structure on top of the proof stack, but also does so for its nested structures. For instance, the second occurrence of `! [...]` will turn the goal $(\exists m, \text{length } m = \text{length } s \wedge w = \text{mask } m \ s) \rightarrow \dots$ into $\forall m, \text{length } m = \text{length } s \rightarrow w = \text{mask } m \ s \rightarrow \dots$ by destructing both the existential quantifier (i.e., the dependent product) and its nested conjunction. The remaining in-place rewrites (via `->`) at the line 7 turn the goal into:

$$\text{subseq } (\text{mask } m2 \ (\text{mask } m1 \ s)) \ s \quad (6)$$

In plain text, we have to show that if we apply `mask` to some sequence `s` with two arbitrary masks, `m1` and `m2`, the resulting sequences would be a subsequence of `s`. Line 8 advances the

proof by induction on s , after generalising the goal over $m1$ and $m2$ and discharging the base case with `//`, which implicitly uses the rewrites allowed by the definition of `mask`.

Next, line 9 performs the case analysis on $m1$. When it is empty, goal (6) becomes `subseq [] s`, which can be automatically reduced to `True` by employing the reflection between `subseq` and `subseqb`. The case when $m2$ is empty is handled automatically in a similar fashion at line 14. We are now left with the following two remaining goals:

- If $m1$ is non-empty and its first element is `false` (lines 11-12), then after all simplifications, goal (6) is reduced to `subseq (mask m2 (mask m1 s)) (x :: s)`, where x is a head of the initial list s . Here we employ the induction hypothesis `IHs1` at line 11, to state that `mask m2 (mask m1 s)` is a subsequence of s , which means that `mask m2 (mask m1 s)` is just `mask m s`, for some `mask m`. To finish the proof we instantiate the existential quantifier in the definition of `subseq` by taking `false :: m`, which, when applied to `x :: s` produces exactly `mask m s` (line 12).
- If the first element of $m1$ is `true`, we perform case analysis on $m2$ (line 14), dispatching the empty case in a way similar to dealing with $m1$ at line 9. When $m2$'s first element is also `true` is trivial as in this case neither of the masks removes the head of s and our goal will simplify to `subseq (x :: mask m2 (mask m1 s)) (x :: s)` and then, by reflection, to `subseq (mask m2 (mask m1 s)) s`, which is trivially implied by the induction hypothesis. All this is done by `//=` at the end of line 14. Finally, the case when $m2$'s head is `false` (lines 15-16) is similar to the proof at lines 11-12.

The proof in Fig. 8 comes from our case study: migrating the MathComp library `seq` from Coq/SSReflect to Lean. In Sec. 4.1 we will further elaborate on this mechanisation effort.

3 Implementing LeanSSR using Lean Metaprogramming

In this section we shed light on the implementation of LeanSSR, which makes extensive use of Lean's metaprogramming facilities. Despite the abundance of available tutorials on implementing tactics in Lean, it still took significant effort to understand how to compose different features to achieve the desired behaviour, following examples from the Lean Metaprogramming Book [22], several research papers [24, 29], Lean source code, and online meetings with Lean developers. This makes us believe that our report on this experience might be of interest even for seasoned Lean users who consider developing their own tactics.

Besides the new LeanSSR-specific tactics, such as `elim`, `scase`, `sapply`, etc., the three essential enhancements made by LeanSSR over the vanilla Lean tactic language are:

1. *Intro patterns*: the set of commands that can follow `=>`
2. *Rewrite patterns*: the set of commands that can follow `srw`
3. *Revert patterns*: the set of commands that can follow :

We refer to those commands as patterns because they are meant to (partially) *match* some part of the goal. The first set, *i.e.*, intro patterns, includes `?`, `*`, `[... | ... | ...]`, etc. The second set, rewrite patterns, includes `eq`, `[i j ...]eq`, `-[i j ...]eq`, etc, where `eq` is an arbitrary equality fact. For the sake of space, we do not detail revert patterns in this paper, but they are fully documented in the README file of the accompanying code repository [8].

The characterisation of the three pattern categories is non-exclusive: some LeanSSR commands, *e.g.*, `//` and `//=`, can be used both as intro patterns (following `=>`) and rewrite patterns (following `srw`). To avoid code duplication, those “last-mile automation” commands themselves form a set of *automation patterns* that are implemented separately and then registered to work in positions of both intro and rewrite patterns.

An informal depiction of LeanSSR patterns can be found in Fig. 9. Each box stands for a separate set of patterns, the arrows denote the dependencies between those sets. In Sec. 3.1–3.3, we discuss the implementation of the components highlighted by grey boxes, concluding with a discussion on LeanSSR support for computational reflection in Sec. 3.4. We do not assume the reader to be familiar with metaprogramming in Lean and will explain the required notions as we progress with our presentation.

■ Fig. 9. High-level structure of LeanSSR

3.1 Syntax, Macros, and Elaboration for the Last-Mile Automation

We start by discussing the three key features of Lean metaprogramming essential for our LeanSSR embedding: (1) syntactic categories, (2) macro-expansion, and (3) elaboration rules, using the implementation of automation patterns as an example. The implementation is shown in Fig. 10. At the high level, we first define a syntax for a sequence of such patterns (lines 1-8), then tell Lean how to execute such a sequence (lines 10-22), concluding with the definition of `sby` tactical. More detailed explanation of the code follows below.

```

1 declare_syntax_cat ssrTriv
2 syntax "/" : ssrTriv
3 syntax "/" : ssrTriv
4 syntax "/" : ssrTriv
5 syntax "/" : ssrTriv
6 syntax "/" : ssrTriv
7 declare_syntax_cat ssrTrivs
8 syntax (ppSpace colGt ssrTriv)* : ssrTrivs
9
10 elab_rules : tactic
11 | '(ssrTriv| /) =>
12   run '(tactic| try dsimp)
13 | '(ssrTriv| /) =>
14   run '(tactic| try simp)
15 | '(ssrTriv| /) => ... -- omitted
16
17 macro_rules
18 | '(ssrTriv| /) => '(ssrTrivs| /)
19 | '(ssrTriv| /) => '(ssrTrivs| /)
20
21 elab_rules : tactic
22 | '(ssrTrivs| $ts : ssrTriv *) =>
23   for t in ts do allGoals $ evalTactic t
24
25 elab sby:"sby " ts : tacticSeq : tactic => do
26   evalTactic ts
27   unless (<- getUnsolvedGoals).length = 0 do
28     allGoals $ run '(ssrTriv| /)
29   unless (<- getUnsolvedGoals).length = 0 do
30     throwErrorAt sby "No applicable tactic"

```

■ Fig. 10. Implementing of last-mile automation in LeanSSR using Lean metaprogramming.

Line 1 defines a *syntactic category* called `ssrTriv` for the LeanSSR automation patterns. One can think of a syntactic category as of a set of syntax expressions grouped together under a single name, for which interpretations can be given. Next, lines 2-6 define elements of this category: `/`, `/`, `/`, `/` and `/`. At line 7, we define yet another syntax category `ssrTrivs` for sequencing automation patterns. Elements of this category are iterated sequences of `ssrTriv` separated with a space `ppSpace`. To ensure that Lean does not try to parse the next line after a sequence of the patterns `ssrTriv` as a its continuation, we also insert the `colGt` element, which allows for line breaks, but only if the column number of the pattern on a new line is greater than the column number of the last pattern on the line above, in the spirit of Landin’s Offside Rule [15].

Having defined the syntax for the automation pattern, we proceed to ascribe semantics to it. Lines 10-15 give a meaning to basic automation patterns by using Lean’s standard mechanism of elaboration rules via the `elab_rules` directive. Each elaboration rule maps a piece of a syntax into an execution inside Lean’s `TacticM` monad [4, §8.3], thus defining a tactic in terms of other Lean tactics, with access to the global proof state. For example, `/` is elaborated into executing the standard `try dsimp` tactic (lines 11-12). The remaining automation patterns, `/` and `/` are defined in terms of the more primitive elements of `ssrTriv`. This is done using Lean’s rules for macro-expansions, following the `macro_rules`

directive. Macro-expansion rules in Lean map elements of syntax into executions within the `MacroM` monad, returning another element of syntax as a result. Those rules are applied by the Lean interpreter after the parsing stage, but before the elaboration stage. Here, we simply expand `/// to /= //, and /// to /== //, as shown at lines 16-18 of Fig. 10.`

Since both `/// and /// are represented as elements of the ssrTrivs category, we have to tell Lean how to elaborate them as well. For the sake of demonstration, we are going to do it by employing one of the most powerful tools in Lean’s metaprogramming toolbox: the evalTactic directive. This directive takes an arbitrary piece of syntax and tries to elaborate it into a sequence of tactics to be executed, using a set of macro-expansion and elaboration rules available in the dynamic context, i.e., the rules available at the usage site in a particular proof script. We will get to experience evalTactic in its full glory in Sec. 3.2. For now, let us highlight one of its most useful features: annotating each token in the given syntax with a correspondent proof state. That is, when elaborating and executing its argument, evalTactic saves the goal before and after executing each token, allowing for the interactive fine-grained proof state exploration we presented in Sec. 2.4.`

Finally, lines 24-30 implement the `sby` tactical (Sec. 2.5). Line 24 defines both its syntax and elaboration using the `elab` directive. The tactical starts with the string “sby” (its position in a concrete syntax tree is bound as `sby`), followed by a sequence of tactics `ts`. We first run this tactic sequence (line 15), then, unless it has solved all goals, we run `/// (lines 26-27). Otherwise, if there are unsolved goals, an error is reported at the sby position.`

3.2 Intro Patterns, Modularity, and Extensibility

Let us now briefly go through the high-level structure of the implementation of intro patterns. While to a large extent similar to that of last-mile automation, this part of our development showcases two new noteworthy aspects of LeanSSR internals. First, we will demonstrate the *modular* nature of pattern definitions by showing how the intro patterns incorporate those for automation. Second, we will show how the intro patterns that come with LeanSSR can be easily *extended* for domain-specific proofs, thus addressing claim (3) from Sec. 1—an aspect of our implementation made possible by the dynamic nature of the `evalTactic` directive.

```

1 declare_syntax_cat ssrIntro
2 syntax ssrTriv : ssrIntro
3 syntax ident : ssrIntro
4 syntax "?" : ssrIntro
5 ...
6 declare_syntax_cat ssrIntros
7 syntax (ppSpace colGt ssrIntro)* : ssrIntros
8
9 elab_rules : tactic
10 | '(ssrIntro| $t:ssrTriv) => evalTactic t
11 | '(ssrIntro|$i:ident) =>
12   run '(tactic| intro $i:ident)
13 | '(ssrIntro| ?) =>
14   run '(tactic| intro _)
15 ...
16 elab_rules : tactic
17 | '(ssrIntros| $is:ssrIntro*) =>
18   for i in is do allGoal $ evalTactic i
19
20 elab t:tactic "=> " is:ssrIntros : tactic =>
21   do evalTactic t; evalTactic is
22 ...
23
24 macro_rules
25 | '(ssrTriv| //) => '(tactic| omega)
26 ...
27 syntax "!" : ssrIntro
28 elab_rules : tactic
29 | '(ssrIntro| !$i:ident) =>
30   run '(tactic| ext)

```

■ Fig. 11. Implementation of LeanSSR intro patterns and their extensions.

Fig. 11 presents a fragment of the implementation of intro patterns for LeanSSR. Following the template outlined in Sec. 3.1, it defines the syntax for a single intro pattern (lines 1-6) and multiple intro patterns (lines 5-7). Now, to allow for last-mile automation within intro patterns, we only have to explicitly add line 10, which, intuitively, says: once you meet a `ssrTriv` inside some `ssrIntro`, just handle it with the already defined macro/elaboration rules. Lines 11-14 provide examples of an intro pattern elaboration rule: a constant introduction with an explicit name `i` (lines 11-12) and with an autogenerated name (lines 13-14),

handled using Lean’s `intro` tactic. Lines 16-18 handle a sequence of intro patterns. Finally, a new tactic `=>` is defined at lines 20-21 to allow use of intro patterns in a proof script.

Lines 24-25 of Fig. 11 show the first example of extensibility afforded by Lean metaprogramming: augmenting the automation pattern `//` to discharge arithmetic facts by calling the standard `omega` tactic. This definition *enhances* the behaviour of the pattern in the entire scope below the macro-expansion rule (keep reading to learn why it does not *replace* the original behaviour of `//`). Another example of extensibility is presented at lines 27-30, integrating a domain-specific tactic into LeanSSR patterns. The mathlib’s `ext` tactic automatically applies extensionality axioms, *e.g.*, turning a goal of the form $f = g$, where both f and g are functions, into $\forall x, f\ x = g\ x$, followed by introduction of x . We integrate it into LeanSSR intro patterns by defining the syntax `!` for it as a new `ssrIntro` pattern at line 27, and by elaborating the `!` pattern to the `ext` tactic at lines 28-30.

The desired effect in both scenarios outlined above is achieved by the two somewhat non-obvious practices we follow in our implementation of LeanSSR patterns:

- (a) The semantics of the patterns is implemented exclusively using the `macro_rules` and `elab_rules` commands, while their evaluation is *always* done using `evalTactic`, which is invoked from the definitions of pattern sequences, as appear in Fig. 10 as Fig. 11.
- (b) Elaboration rules for each particular pattern are defined separately from others.

Following these practices makes it possible to extend LeanSSR with new `macro_rules` and `elab_rules` in a modular fashion. To extend LeanSSR with a new pattern or add a new behaviour, it suffices to just add a new elaboration/macro rule for it. The reason why it works follows from the way `evalTactic` performs the bookkeeping of the macro/elaboration rules and their application. Any new such rule is added at the top of a *rule database stack*. Whenever `evalTactic` is invoked (*e.g.*, when elaborating and executing a particular sequence of intro patterns as per line 18 of Fig. 11), it will go through the stack of the saved rules, starting from the top, until it either finds the first one that executes without errors (*i.e.*, without throwing an exception as in Fig. 10 at line 29), or exhausts the stack.³

In particular, in case of `//` supplied with the rule at the lines 24-25 of Fig. 11, `evalTactic` will first try to expand it into `omega`. If `omega` executes without errors (this is only possible if it solves the goal completely), `evalTactic` looks no further. If `omega` fails, leaving the goal unchanged, `evalTactic` proceeds with the next option on the rule stack, *i.e.* the one at line 15 of Fig. 10 (assuming no other registered rules for `//`). This is the reason why lines 24-25 of Fig. 11 *do not alter* the behavior of `//` but augment it with `omega`.

3.3 Rewrite Patterns and Custom Environment Extensions

The implementation of LeanSSR rewrite patterns relies on yet another very useful feature of Lean metaprogramming: *custom environment state extensions*. The need for environment state extensions comes from the rather restrictive format of `evalTactic`, which takes only one argument: the syntax of the tactic to elaborate and run. Therefore, the execution of a tactic implemented via `evalTactic` can only depend on the general proof environment, *i.e.*, the proof context and the set of all available definitions available at the point of its invocation. So far, this has been sufficient for our needs to implement patterns for automation and introduction that were “context-independent”. The behaviour of a useful tactic for rewriting is a bit more complex, since this tactic is expected to take a rewrite *location*, *i.e.*, a local hypothesis or the goal (its default behaviour). While the location of a rewrite is accessible

³ It is a good practice to put elaboration into tactics, which either fully solve the goal or fail otherwise, closer to the top of the stack, so they would not be preempted by elaboration into tactics that never fail.

```

1 declare_syntax_cat ssrRw
2 syntax ssrTriv : ssrRw
3 syntax term:max : ssrRw
4 declare_syntax_cat ssrRws
5 syntax (ppSpace colGt (ssrRw))* : ssrRws
6
7 abbrev LocationExtState := Option
8   (TSyntax 'Lean.Parser.Tactic.location)
9
10 initialize locExt :
11   EnvExtension LocationExtState ←
12     registerEnvExtension (pure none)
13
14
15
16 elab_rules : tactic
17 | '(ssrRw| $t:ssrTriv) =>
18   evalTactic t
19 | '(ssrRw| $i:term) => do
20   let l <- locExt.get
21   run '(tactic| rw [$i:term] $(l?))
22 ...
23
24 elab "srw" rs:ssrRws l:(location)? : tactic => do
25   locExt.set l
26   evalTactic rs
27

```

■ **Fig. 12.** Implementing rewrite patterns by passing the rewrite location in a local state extension.

at the level of the entire tactic command, it cannot be directly passed to `evalTactic` when elaborating each individual rewrite pattern, as the pattern itself is `evalTactic`'s sole argument. Custom environment state extensions solve this issue by providing access to *additional state* that can be used to store such data when elaborating a top-level command, making its accessible for the elaboration rules of its inner components (*i.e.*, the patterns).

To demonstrate the use of this technique, Fig. 12 shows an implementation of a restricted version of `LeanSSR` rewriting, which only supports rewrites of the form:

`srw Eq1 // Eq2 Eq3 // ...`

In other words, it only allows for rewriting with equality facts (*i.e.*, `Eq1`, `Eq2`, *etc.*) and for employing last-mile automation to solve the generated sub-goals. Importantly, our example also allows for rewriting at a specified hypothesis `H` from the local context using `srw ... at H` syntax. The syntactic category for rewrite patterns is defined at lines 1-5 of Fig. 12. It includes automation (line 2) and ordinary Lean terms (line 3). Preparing to pass the rewrite location around as an additional state component, we first define a type of the state extension `LocationExtState` (lines 7-8). It is an option, where `some ...` denotes a local hypothesis to rewrite at, and `none` stands for the goal. Next, the `initialize` command registers the custom state component of the type `LocationExtState` with the name `locExt`, storing `none` to it as a default value (lines 10-12). Fast-forward to lines 24-26, the elaboration rule for `srw` first sets the value `locExt` to the optional argument `l`, *i.e.*, the hypothesis passed after `at` or the goal, if that part is omitted. Finally, the elaboration rule for named rewrite patterns (*i.e.*, equality facts) at lines 19-21 first fetches the location from the `locExt` component of the extended state, and then executes Lean's native rewrite tactic `rw` at that location.

3.4 Computational Reflection via Type Classes

We conclude this section by discussing the implementation of computational reflection in `LeanSSR` via Lean type classes and its interaction with `Decidable` instances.

Lines 1-4 of Fig. 13 provide the definition of the `Reflect` predicate adopted almost verbatim from `SSReflect` (we will explain the `outParam` keyword below). Lean users can notice that `Reflect` is very similar to `Decidable` with the only difference being that the former mentions the Boolean representation of the decidable predicate explicitly. The `#reflect` command at line 10 will use this explicit Boolean representation `b` to generate reduction/rewrite rules for the respective predicate `P`. This simplification machinery for propositions is generated from their corresponding symbolic counterparts in two steps:

- (i) The reduction principles of symbolic representations are retrieved as quantified equalities.
 - (ii) Boolean functions in those equalities are replaced with their corresponding propositions.
- Step (i) comes “for free”: to partially evaluate recursive definitions, Lean automatically generates lemmas in the form of quantified equalities representing the available reductions.

```

1 class inductive Reflect (P : Prop) :
2   (b : outParam Bool) -> Type
3   | T (_ : P) : Reflect P true
4   | F (_ : ¬ P) : Reflect P false
5
6 theorem toPropEq (_ : b1 = b2)
7   [Reflect P1 b1] [Reflect P2 b2] :
8   P1 = P2 := ...
9
10 elab "#reflect" P:term b:term : command => ...
11
12 macro "reflect" : attr => '(attr| default_instance)
13 @[reflect] instance tP : Reflect True true := ...
14 @[reflect] instance : Reflect False false := ...
15 @[reflect] instance [Reflect P1 b1] [Reflect P2 b2]
16   : Reflect (P1 ∧ P2) (b1 && b2) := ...
17 @[reflect] instance [Reflect P1 b1] [Reflect P2 b2]
18   : Reflect (P1 ∨ P2) (b1 || b2) := ...
19 ... -- other basic reflect predicates
20 instance [Reflect P b] : Decidable P := ...

```

■ Fig. 13. A fragment of computational reflection implementation in LeanSSR.

For example, for the `evenb` definition from Fig. 7 in Sec. 2.6 Lean will generate tree lemmas:

```

eq1: evenb 0 = true      eq2: evenb 1 = false
eq3: ∀ n, evenb (n + 2) = evenb n

```

Those lemmas are then implicitly used by the `simp` and `dsimp` tactics in Lean proofs.

With all those equalities at hand, step (ii) is achieved with the help of the `toPropEq` lemma (lines 6-8) that derives the equalities on propositions out of equalities on their Boolean counterparts. For example, applying `toPropEq` to the quality `eq1` above will give us the equality `even 0 = True`, assuming we also somehow synthesise its two implicit `Reflect` instance arguments. The synthesis is enabled by the following LeanSSR components.

The first one is a library of `Reflect`-lemmas connecting standard logic connectives, such as $\wedge$ and $\vee$ with their computational counterparts, *i.e.*, `&&` and `||`. The need for those lemmas arises when we need to synthesise a propositional version of a symbolic expression that does not have an application of the function in question at the top level. In particular, while the left-hand side of all retrieved equalities is always a function applied to some arguments (*e.g.*, `evenb (n + 2)`), the right-hand-side might be an arbitrary expression containing other symbolic logical constants and connectives. The various `Reflect`-lemmas (lines 12-18 of Fig. 13) provide recipes for synthesising *proofs* for the corresponding logical counterparts in a way similar to type class instance resolution in Haskell. LeanSSR provides a collection of such lemmas, and the user can add their own, extending the reflection in a modular fashion.

Alas, the type class resolution mechanism of Lean will not immediately work as desired. For example, when we apply `toPropEq` to `eq1`, it will have to work out two instantiations (*i.e.*, proofs): for `Reflect ?P (evenb 0)` with `?P := even 0` and for `Reflect ?Q true` with `?Q := True` (line 12). By default, Lean's algorithm for synthesising instances will fail due to a simple reason: to construct an instance of, *e.g.*, `Reflect ?P (evenb 0)` it *must know* what that `?P` is. That is, the algorithm will only attempt to synthesise an inhabitant for a fully instantiated type class signature, but not for the one that has variables. To fix this, we use the mechanism of *default instances*, *i.e.*, proof terms that are available for instance search even when not all type class arguments are known [5, §4.3]. For example, marking `tP : Reflect True true` as a default instance will make the type class resolution algorithm aware of it, thus, finding a suitable instantiation for `?Q` in the process. For readability, LeanSSR provides a `reflect` notation for the `default_instance` attribute, so that `Reflect` instances can be marked as default ones simply by tagging them with `@[reflect]`.

The last bit of our implementation is a link between `Reflect` and `Decidable`. Once a `Reflect` instance for a logical predicate `P` is provided, LeanSSR also generates its decidable instance (line 20 of Fig. 13), *e.g.*, to use this `P` in any position that requires a Boolean expression. Marking the parameter `b` of `Reflect` as `outParam` (line 2) is essential for this: it tells the instance search algorithm that `b` is not required for finding the instance (since `P` already provides enough information), and should be treated as the output of the synthesis.

```

1 Lemma subseq_trans: transitive subseq.
2 Proof.
3 move=> _ _ s /subseqP [m2 _ ->] /subseqP [m1 _ ->].
4 elim: s m1 m2 => [*|x s IHs]; first by rewrite !mask0.
5 case=> [*|[] m1 m2]; first by rewrite !mask0.
6 { case: m2=> [/|=|[] m2] //; first by rewrite /= eqxx IHs.
7   case /subseqP: (IHs m1 m2) => m sz_m ?; apply/subseqP.
8   by exists (false :: m); rewrite /= sz_m. }
9 case/subseqP: (IHs m1 m2) => m sz_m ?; apply/subseqP.
10 by exists (false :: m); rewrite /= sz_m.
11 Qed.

```

■ Fig. 14. SSReflect proof of the theorem in Fig. 8b. Parts not needed in LeanSSR are highlighted.

4 LeanSSR in the Wild: Case Studies

In this section, we showcase two examples that support our claims from Sec. 1, by demonstrating LeanSSR’s expressivity compared to Coq/SSReflect and to vanilla Lean, highlighting the more compact proof scripts we obtain, as well as the overall usability of our approach.

4.1 Migrating MathComp Sequences to LeanSSR

To evaluate LeanSSR against SSReflect, we ported a small subset (approximately 10%) of the finite sequences file from the Mathematical Components library Coq [18], amounting to 31 definitions, 72 theorems, and 3 reflection predicates. As the logics of Lean and Coq are similar, and MathComp is implemented in SSReflect, which is syntactically very similar to LeanSSR, most proofs can be translated almost mechanically, with minimal changes.

Our proofs are nonetheless more compact than the originals for two reasons: (a) the user does not need to explicitly switch between logical and symbolic representations of the goal (claim 2) and (b) many rewrites can be performed by LeanSSR’s simplification mechanism, due to its extensibility (claim 3), and do not need to be invoked manually. A representative example can be seen in Fig. 14, which shows a SSReflect proof (slightly modified from the original for presentation purposes) of the fact that the subsequence relation is transitive. The LeanSSR equivalent was shown previously in Fig. 8b. The Lean version is more compact as it requires neither the explicit invocations of the reflection predicate (highlighted in red in Fig. 14) nor various trivial rewrites (highlighted in orange), which can be performed automatically by LeanSSR’s powerful and extensible `//` automation. Overall, this amounts to a reduction in half of the size of each line of proof, and we argue, to a reduction of the cognitive effort required of the user, who can now focus on the essential aspects of the proof, delegating trivial details to automation. Indeed, many simple statements can be proven in LeanSSR by `elim: s=>//=`, reminiscent of the `induct-and-simplify` tactic of PVS [21, 28].

4.2 Refactoring mathlib

To evaluate LeanSSR against proofs in mathlib [19], we ported a few facts about cardinalities of finite sets. Fig. 15 presents two proofs of a *subgoal* for the `card_eq_of_bijective` lemma from mathlib: the original proof and one ported to LeanSSR. The subgoal states that for a bijective function `f` from a range of all natural number less than `n`, each element in this range has a pre-image *w.r.t.* `f`. Notably, mathlib proofs frequently build a proof term explicitly, rather than via tactics. In cases like the one in Fig. 15, such manual proof term construction tends to be more concise than the respective proof script, hence the ubiquity of this mechanisation style in mathlib. The same proof ported to LeanSSR is shown in Fig. 15b. Here, the `< .. | ... | .. >` pattern is similar to `[ .. | ... | .. ]`, but instead

<pre> 1 example 2 (hf : ∀ a ∈ s, ∃ i (h : i < n), f i h = a) 3 (hf' : ∀ i (h : i < n), f i h ∈ s) : 4 ∀ (a : α), a ∈ s ↔ 5 ∃ i, ∃ (hi : i ∈ range n), f i _ = a := 6 fun a => 7 ⟨fun ha => 8 let ⟨i, hi, eq⟩ := hf a ha 9 ⟨i, mem_range.2 hi, eq⟩, 10 fun ⟨i, hi, eq⟩ => eq ▸ hf' i (mem_range.1 hi)⟩ </pre>	<pre> 1 example 2 (hf : ∀ a ∈ s, ∃ i (h : i < n), f i h = a) 3 (hf' : ∀ i (h : i < n), f i h ∈ s) : 4 ∀ (a : α), a ∈ s ↔ 5 ∃ i, ∃ (hi : i ∈ range n), f i _ = a := 6 by move=> a 7 ⟨/hf ! [i /mem_range ? <-] // 8 ! [i /mem_range /hf' / [swap]->] //⟩ </pre>
--	---

(a) Original mathlib proof script

(b) LeanSSR proof script

■ **Fig. 15.** Two proofs of the same fact from mathlib: the vanilla one and the one in LeanSSR.

of matching on the top element of the goal stack, it applies the `constructor` tactic to the goal, and runs nested tactics on the generated subgoals. The main difference between those two proofs is that instead of the somewhat awkward backward-style reasoning with explicitly constructed proof terms (*e.g.*, line 10 in Fig. 15a), LeanSSR allows for natural forward-style proofs using LeanSSR views (*cf.* Sec. 2.5). Specifically, the mathlib proof of the second component of the bi-implication from the conclusion (*i.e.*, right-to-left) first destructs the hypothesis $\exists i, \exists (hi : i \in \text{range } n), f i _ = a$, and then gradually reduces the goal $(a \in s)$ to the assumption $hi : i \in \text{range } n$ by first rewriting `eq`, then applying `hf'` and finally `mem_range : n ∈ range m ↔ n < m`. In contrast, the LeanSSR proof adapts `hi` to solve the goal automatically at line 8 of Fig. 15b, by first applying `mem_range` to its second existential, then `hf'` to the result, and then rewriting `eq` in it via the special form of the view pattern `/ [swap]`, followed by `->`.

We claim that the presented LeanSSR proof has certain advantages compared to the one from mathlib. First, views will automatically infer dependent arguments when applying a lemma, *e.g.*, `i` in `hf' i mem_range.1 hi` at line 10 of Fig. 15a. Second, LeanSSR organically incorporates last-mile automation (using `//` and other automation patterns) to the forward-style proof script, thus, sparing the user the effort of building yet another collection of proof terms to dispatch the subgoals. Finally, unlike the proof terms constructed holistically, LeanSSR proofs are interactive: one can check the intermediate subgoals by simply pointing to the specific location in the text buffer, resulting in a better overall proof experience. In summary, our experiment demonstrates that LeanSSR proofs are not only shorter compared to the original mathlib ones, but also easier to follow and debug. The latter aspect is crucial for the long-term maintainability of large formal Lean developments such as mathlib.

5 Related Work and Conclusion

Prior to our effort, Lean 4’s metaprogramming facilities have been used to implement white-box automation via proof search in the popular Aesop package [17]. In particular, mathlib [19] uses Aesop to build domain-specific solvers such as `measurability` and `continuity`, and uses metaprogramming extensively to define its own tactics and automation facilities (*e.g.*, `split_ifs` and `linarith`). Closer in spirit to our work, König developed a proof interface in Lean in the style of Iris proof mode [13], featuring a specialised tactic language for proofs in Separation Logic [14]. In Lean 3, Limperg built an induction tactic that is friendlier for novices by giving the most general induction hypothesis [16].

We believe that our implementation of LeanSSR provides an instructive example of using Lean 4 metaprogramming features for implementing a non-trivial tactic language, and adds one more arrow to the quiver of tools and techniques for proof construction in Lean.
