Abstract

We investigate the magnetic properties of Fe Phthalocyanines (FePc) that are experimentally arranged in quasi one-dimensional chains when they are grown in thin films or powders. By means of DFT calculations we reproduce the structural parameters found in experiments, and then we build a generalized Heisenberg magnetic model with single ion anisotropy, and calculate its parameters. The results show a anisotropic exchange interaction J between FePc molecules, and an easy plane single ion anisotropy D. By means of Monte Carlo simulations, with this model, we found an explanation to the non-saturation of the magnetization found at high fields, which we interpret is due to the anisotropic exchange interaction J. Finally, we also investigate the presence of magnetic solitons versus temperature and magnetic field. This results provide additional evidence that FePc is a soliton bearing molecular compound, with solitons easily excited mainly in the molecular xy plane.

Introduction

Over the past decade, significant progress has been made in the field of organic materials due to their potential applications as nanoscale spintronics,¹ organic photovoltaics,^{2,3} transistors,^{4–6} light-emitting diodes,^{7,8} and electrochemical devices.^{9,10} Organic materials constructed with one-dimensional building blocks, in particular, have become a subject of great interest because they serve as excellent model systems for studying and applying low dimensional magnetic phenomena. It is important, then, to understand the underlying principles of their magnetic properties. Among the building blocks for organic materials, metal phthalocyanines (MPcs) are one of the most extensively used.¹¹

The MPc molecule is composed of a conjugated planar macrocycle, $MN_8C_3H_{16}$, with M being a central metal atom that is 4-coordinated to the N isoindole or pyrrole N atoms, N_{py} . The macrocycle is made up of four isoindole units linked by a ring of four N atoms (N_{bridge}), as shown in Fig.1(a). Depending on the growth conditions, MPc crystallizes into a range of polymorphs, that have been observed in powders, thin films (TF), and nanowires systems.¹¹ The building blocks of these crystalline forms are one dimensional (1D) columns, composed of MPc molecules, with the metal atom M at the center serving as the column axis, or the stack axis (see Fig.1(d)). The stacking columnar structures differ in the tilting angles (φ) between the stacking axis and the molecular plane, and the interplanar distance (d) between two neighboring molecular planes along the column, resulting in different Pc crystal structures (see Fig.1(c)).^{11–17} Modifying the magnetic center of MPc introduces an additional degree of freedom to the properties of its polymorphs, since it impacts the magnetic properties of the molecule and hence of the crystals formed by them.

Two different arrangements have been proposed to describe the stacking geometry of MPc molecules. The first one is referred to as the herringbone structure, where the molecules stack with opposite angles between adjacent columns.¹⁸ In the second one, the MPc molecules stack in the same orientation in each column, forming the so-called brickstack structure.¹³

Particularly, iron phthalocyanines (FePc) are a class of MPc molecules that have garnered

significant attention. In bulk arrangements, FePc exhibits two polymorphs, α and β , with stacking angles of 26.5° and 44.8°, respectively. Previous studies of the β phase have shown that it behaves paramagnetically.¹⁹ However, in the α phase found in powder systems, FePc shows ferromagnetic correlations below approximately 10 K.¹⁹ The evidence in powders points to an arrangement of the herringbone type.²⁰ On the other hand, in thin films (TF), FePc molecules adopt a brickstack structure when grown on a variety of substrates.^{12,14,17,21} The polymorphism found in TF has been called α_{+}^{13} (but it has also been directly called α^{14} or TF¹⁷), since, besides the brickstack arrangement, it is different from the bulk α phase from the way each molecule is shifted with respect to the one in the upper/lower molecular plane (see section Stacking Geometry below for more detail). In this work we will refer to this polymorphism as α_{+} . FePc thin films have been reported to become ferromagnetically correlated at temperatures below 20 K¹⁴ and exhibit a ferromagnetic transition at 4.5 K,²² very similar to the transition temperature in powders at 5 K.¹²

In order to explain the magnetic phenomena observed in experiments, both in powders and in TF, different model Hamiltonians have been proposed. Moreover, even the same parameters have very different proposed values in different works (see section Magnetic Model below for more details). On the experimental side, magnetization measurements made in powders and also also in TF show that at relatively high magnetic fields, the magnetization does not saturate.^{14,19} In the case of powders, this non saturation has been attributed to the herringbone arrangement, due to the canting of the adjacent columns of FePc molecules.¹⁹ However, in thin films the arrangement is of the brickstack type,²⁰ so that other mechanism must be also contributing to the non saturation of the magnetization as well. Finally, in a recent work, experimental evidence of magnetic solitons has been found.¹⁴ Since FePc has gained attention partly because of their electrical and magnetic properties, it is important to study how magnetic solitons are developed in this system. In order to shed light on these issues, a theoretical study beginning from first principles calculations ending in a magnetic model was carried out, to help to understand this and related systems further.

Figure 1: (a) FePc molecule view from top. The four Nitrogen closer and farthest to the Fe atom are the pyrrole (N_{py}) and the bridging (N_{bridge}) nitrogen atoms, respectively. Fe, N_{py} , N_{bridge} , C and H are indicated by red, cyan, blue, gray and white balls, respectively. (b) and (c) Stacking geometry of FePc-film. *d* is the distance between the molecular planes and φ is the angle between the stacking axis \bar{u}_3 and a vector perpendicular to the molecular plane. (d) The cell parameters for a supercell containing 1 molecule are $|\bar{u}_1| = 13.24$ Å, $|\bar{u}_2| = 13.43$ Å, $|\bar{u}_3| = 3.60$ Å, $(\bar{u}_1, \bar{u}_2) = 85^\circ$, $(\bar{u}_1, \bar{u}_3) = 63.6^\circ$, $(\bar{u}_2, \bar{u}_3) = 74.1^\circ$. It is important to take into account that for the magnetic model, we employed a cell size that is doubled in the \bar{u}_3 direction and contains two molecules per cell.

In this work we theoretically study the α_+ phase of FePc chains, by means of density functional theory (DFT) and classical Monte Carlo. With DFT calculations, we first obtain structural parameters, comparing with available experimental data, and then proceed to calculate the parameters of a generalized Heisenberg model with single ion anisotropy. We obtain a anisotropic Heisenberg model, with an easy plane single ion magnetic anisotropy D and negligible E. Afterwards, we study this model in an array of weakly coupled FePc chains, by means of classical Monte Carlo simulations. We were able to explain the lack of saturation observed in magnetization experiments. Finally, we investigate the magnetic excitations of this system, focusing on exploring the existence of solitons in the phase diagram.

Methods

Computational Details

DFT calculations were performed with the VASP code^{23–28} within the slab-supercell approach and using the projector augmented-wave (PAW) method.²⁷Wave functions were expanded using a plane wave basis set with an energy cut-off of 550 eV. Different schemes were tested in order to improve the description of vdW interaction: the PBE+D3²⁹ approach and the optB86b-vdW, optB88-vdW, optPBE-vdW, vdW-DF2 non-local correlation functionals.³⁰ From test calculations for the bulk-like FePc structure, we conclude that the optb86b scheme is the one that gives the best interplanar distance with respect to the experimental value, therefore, it is used for the structural determination of bulk structures. However, when calculating the parameters of the magnetic model, in particular the anisotropy parameters D and E, which require spin-orbit interaction turned on, opt86b is not suitable, and the PBE+D3 scheme is used instead (see section magnetic model). Exchange coupling parameters J_x , J_y and J_z are also calculated within this PBE+D3 scheme. For testing purposes, in an isotropic Heisenberg model the exchange coupling J has no appreciable difference when calculated with PBE+D3 or with optb86b.

The Hubbard U correction is considered with the DFT+U approximation³¹ to deal at DFT level with the Fe d-electrons. $U_{eff} = U - J = 3eV$ was chosen, since this value has also been used in previous studies in FePc molecules.^{32,33}

The FePc α_+ polymorphism was studied. For testing purposes, results for the gas phase of FePc are also presented here. Gas phase calculations were carried out at Γ point. For the α_+ phase, the *k-point* grid was 2x2x15. Calculation without and with spin-orbit coupling (SOC) have been performed. Calculations with SOC were carried out at fixed geometry. In all cases, *k* point convergences were achieved. All geometry optimizations were carried out until the forces on every mobile atom were smaller than 0.02 eV/Å, and all calculations were spin polarized.

Gas Phase calculations

Despite the numerous theoretical and experimental studies there is still no definite consensus about the ground state of the molecule. However, there is a broad consensus that the FePc molecule in gas phase has spin S = 1. DFT studies have predicted ${}^{3}A_{2g} \left[\left(d_{z^{2}}^{\uparrow\downarrow} \right) \left(d_{xx,yz}^{\uparrow\downarrow} \right) \left(d_{xy}^{\uparrow\downarrow} \right) \right]^{34}$, ${}^{3}E_{g}(a) \left[\left(d_{z^{2}}^{\uparrow\downarrow} \right) \left(d_{xy}^{\uparrow\downarrow} \right) \right]^{35,36}$ and ${}^{3}B_{2g} \left[\left(d_{z^{2}}^{\uparrow\downarrow} \right) \left(d_{xx,yz}^{\uparrow\downarrow} \right) \left(d_{xy}^{\uparrow\downarrow} \right) \right]^{37}$ as possible ground states and the prediction actually depends on the choice of the exchange-correlation (XC) functionals.³⁸ The same conclusion has been established by a recent work based on a diffusion Monte Carlo study where they obtain mainly ${}^{3}A_{2g}$, but also ${}^{3}B_{2g}$ and even ${}^{3}E_{g}$ depending on XC.³⁹ A recent theoretical work employing numerous and sofisticated methodologies has concluded that the ground state of the molecule is ${}^{3}A_{2g}^{40}$.

Within our calculation, we obtained ${}^{3}E_{g}(a)$ as the ground state (GS), a ${}^{3}A_{2g}$ state at 36 meV and ${}^{3}B_{2g}$ at 279 meV higher energy in line with the results obtained by Ichiba et al. ³⁹ for DFT+U calculations with U=4eV, and also with Ref. ⁴¹ However, as mentioned earlier, in the isolated molecule, numerous configurations appear to be closely competitive. For instance, in our case, the energy difference between ${}^{3}E_{g}(a)$ and ${}^{3}A_{2g}$ is merely 36 meV. Sophisticated methods like those of Refs. ^{39,40} need to be employed to obtain a definite answer to the GS of the isolated molecule. Our focus will be on FePc chains on TF, where the situation seems to be different (see below). Finally, for all electronic configurations, the spin magnetic moment of the molecule is close to $2\mu_{b}$ concentrated in the Fe center.

Figure 2: Directions were the total energy was computed in DFT calculations including SOC. Perpendicular to the molecular plane (001) and two in plane orthogonal directions (100 and 010), respectively.

α_+ phase. Stacking Geometry

In FePc TF grown on different substrates, molecules stack layer by layer almost parallel (with a tilting angle of 7 or 9 degrees) to the substrate surface.^{14,17,21} In this "flat-lying" configuration, two adjacent molecular layers are shifted a distance Δ (see Fig. 1(c)) apart from one another along the Fe-N_{py} bond direction indicated by the *a*, or alternatively the *b*, axis in Fig.1(a). As a result, the Fe atom in a molecule is close to the center of a N_{py} atom in the molecule beneath it^{14,17} (see Fig.1(b)). In this stacking geometry Fe atoms form parallel unidimensional chains that deviate from the normal to the molecular plane by an angle φ (see. Fig.1(c)). In the case of the herringbone arrangement found in powders, apart from the two-sublattice canted structure the other difference is that the shift between FePc molecules occurs along the Fe-N_{bridge} bond.¹⁷ In the case of a FePc TF grown on Au(111),¹⁷ a structural refinement based on XLPA simulations gives $\Delta=1.48$ Å, which is very close to the estimated value from STM images, $\Delta=(1.0 \pm 0.3)$ Å. The distance between adjacent molecular planes is $d_z = 3.25$ Å, and molecules within the molecular plane form a square lattice with a lattice parameter of 13.0 ± 0.2 Å¹⁷ (see Fig.1(d)).

The estimated experimental values for FePc TF grown on PTCDA/Si(100)¹⁴ are $d_z = 3.42$ Å and a distance $d_{Fe-Fe} = 3.77$ Å between the nearest Fe atoms within a chain.

In the case of FePc TF grown Au-coated sapphire, $d_z = 3$ Å and the lateral separation between chains is about 13 Å.²¹ Similar values, with slightly varying, thickness-dependent, stacking angles, have been found in a recent study of FePc films in different substrates.⁴² The similarities in structural data reported for FePc-TF in the "flat-lying" configuration suggest that once layer-by-layer growth is initiated due to the templating effect of the substrate,¹⁵ intermolecular interactions seem to drive the film structure. This leads to performing DFT structural calculations without including the substrate.

We have performed DFT calculations for bulk-like structures with one molecule per unit cell, simultaneously optimizing the unit cell and the molecular degrees of freedom, with the aim of reproducing to the most FePc-TF structure. For the obtained lowest energy structure, the shift of two adjacent layers runs along Fe-N_{py} bond axis¹, with a distance of $\Delta = 1.61$ Å. The distance between molecular planes, the stacking angle of the Fe chain and Fe-Fe distance within a chain are, respectively, $d_z = 3.22$ Å, $\varphi = 26.6^{\circ}$ and $d_{Fe-Fe} = 3.60$ Å. Furthermore, the dimensions of the unit cell vectors u₁ and u₂ and the angle among them are 13.2 Å, 13.4 Å and 85°, respectively. Because the molecular plane is close to the defined plane by u₁ and u₂ ² their dimensions can be compared to the lateral distance between chains experimentally measured. Overall, all parameters agree well with the previously described experimental data, lending support to the DFT calculations for the α_+ phase. For this stacking geometry, the calculations show that each molecule is in a $E_g(a)$ configuration $((d_{z^2}^{\uparrow}) (d_{xz,yz}^{\uparrow\downarrow}) (d_{xy}^{\uparrow\downarrow}))$. This result coincides with previous constrained DFT calculations⁴¹ and with experimental evidence,^{20,43} altough other works predict a ground state in TF that is a superposition of ${}^{3}A_{2g}, {}^{3}B_{2g}$ and ${}^{3}E_{g}$.⁴⁴

Finally, the calculated spin magnetic moment in the Fe atom is $m_s(Fe) = 2.021 \mu_b$, corresponding to S = 1, the same than in the gas phase.

¹The deviation is less than 2°

²The angular deviation is $\sim 4^{\circ}$

Results and discussion

Magnetic model

On the basis of experimental evidence, several magnetic models have been proposed for the bulk phase α and for the TF α_+ of FePc. There is consensus that the molecule has S = 1, and also that there is a positive single ion magnetic anisotropy D, aside from the ferromagnetic exchange J. Working with powders of FePc molecules, Evangelisti *et.* al^{19} observed that the magnetization did not saturate even at high magnetic fields, and this was interpreted in terms of the above mentioned herringbone arrangement, a canted structure between two different magnetic sublattices originally proposed for MnPc. An effective Ising S = 1/2 model was proposed. This Ising model was later backed up in Ref.²⁰ However, it was not considered as appropriate to account for the observed behaviour in TF in Ref.,¹⁴ and an isotropic Heisenberg model with single ion anisotropy was proposed instead. As for the mechanism for the magnetic exchange, in Ref.¹⁹ the direct Fe-Fe interaction was proposed, which renders the interaction ferromagnetic in character. However, the value proposed for the exchange parameter J/k_B or J_z/k_B varies significantly. In a Ising model written as $-2J_z \sum_i S_{z,i}S_{z,i+1}$ for powder samples, it was estimated to have the value of 25.7K in Ref.¹⁹ and 76K in Ref.²⁰ . In isotropic Heisenberg models $-J\sum_i S_i S_{i+1}, J/k_B$ was estimated to be 20K in Ref.¹⁴ and 13K in Ref.,⁴² these last two working on TF. On the other hand, while there is a consensus that the magnetic anisotropy D is positive, indicative of an easy plane situation, its value has been estimated from experiments, varying from D = 92 K in Ref.⁴⁵ to D = 53K in Ref.¹⁴

Spin orbit interaction energy is important in FePc molecules, since they present a high unquenched orbital moment.^{20,43} In this case, it is well known that an effective spin hamiltonian can be derived, which contains terms of the form $DS_z^2 + E(S_x^2 + S_y^2)$, being the parameters D and E matrix elements proportional to the orbital magnetic moment. The D_{4h} symmetry present in isolated FePc molecules is broken when the chains are formed in

the bulk or thin film structure, since the stacking axis is not perpendicular to the molecular plane. This suggests the idea that the Heisenberg exchange term may in principle be anisotropic. An extreme case of this is precisely the Ising model considered in Ref.¹⁹ However, most recent works in FePc bulk structures or TF have considered the isotropic Heisenberg model only.^{14,21,46} On the other hand, the interchain exchange is expected to be relatively small, due to relatively large lateral distances between Fe centers, as confirmed by calculations done in CrPc chains.⁴⁷ These considerations render FePc thin films to be treated, as DFT calculations are concerned, as one dimensional chains of FePc molecules, geometrically arranged as described in section Stacking Geometry, with the possibility of anisotropic magnetic exchange and with other spin-orbit derived interactions present, such as single ion magnetic anisotropy terms. On the other hand, regarding the Dzyaloshinskii-Moriya (DM) anisotropic exchange, it's important to consider that its order of magnitude is given by $D_{DM} \sim (\Delta(g)/g)J$.⁴⁸ With the most recent estimation of g in TF, $g = 2.16^{14}$ the magnitude can be estimated in $D_{DM} \sim 0.08J$. Consequently, this interaction has not been considered significant in this work.

With all this considered, the proposed model Hamiltonian for the one dimensional chains of FePc molecules in the α_+ polymorphism is:

$$H = \sum_{i} D(S_{i}^{z})^{2} + \sum_{i} E(S_{ix}^{2} - S_{iy}^{2})$$

$$- \frac{1}{2} \sum_{\langle i,j \rangle} J_{z}(S_{i}^{z} \cdot S_{j}^{z}) - \frac{1}{2} \sum_{\langle i,j \rangle} J_{x}(S_{i}^{x} \cdot S_{j}^{x})$$

$$- \frac{1}{2} \sum_{\langle i,j \rangle} J_{y}(S_{i}^{y} \cdot S_{j}^{y})$$
(1)

where the sum over i runs over all Fe atoms in the supercell and the notation $\langle i, j \rangle$ represents first neighbor atoms. The factor 1/2 is introduced to avoid double counting. The first term in the Hamiltonian describes the uniaxial anisotropy as we choose z as the off-plane direction. The second term describes the in-plane anisotropy. The anisotropic exchange interaction is considered in the last three terms.

We now proceed to compute the magnitude of the parameters of the model Hamiltonian with DFT calculations, by means of the widely used method of energy mapping.^{49,50} To do so, the energy difference between classical configurations, described in Ec. 2, has been computed.

$$E_x^{FM} = 2ES^2 - 2J_xS^2 + E_0$$

$$E_x^{AF} = 2ES^2 + 2J_xS^2 + E_0$$

$$E_y^{FM} = -2ES^2 - 2J_yS^2 + E_0$$

$$E_y^{AF} = -2ES^2 + 2J_yS^2 + E_0$$

$$E_z^{FM} = 2DS^2 - 2J_zS^2 + E_0$$

$$E_z^{AF} = 2DS^2 + 2J_zS^2 + E_0$$
(2)

Such calculations were performed for a chain defined by two molecules per unit cell. For each configuration the directions x, y, z are defined as in Figure 2. In each line of Eq. 2, $E_{direction}^{FM/AFM}$ is defined, where FM means that the magnetic moments of both molecules are parallel and AFM, antiparallel. For determining the parameters J_x , J_y , J_z , D and E we used the ground state energy obtained from our DFT calculations for each configuration in equation 2. Then, the parameters expressed as function of the ground states energies were

$$J_i = \frac{E_i^{AF} - E_i^{FM}}{4S^2} \tag{3}$$

$$D = \frac{1}{2} \left[E_z^{FM} - \frac{E_x^{FM} + E_y^{FM}}{2} + 2(J_z - \frac{J_x + J_y}{2}) \right]$$
(4)

$$E = \frac{1}{4} \left[E_x^{FM} - E_y^{FM} + 2(J_x - J_y) \right]$$
(5)

where the index i runs for x, y, z.

The obtained results for the Heisenberg exchange were $J_x = 1.77$ meV, $J_y = 2.31$ meV and $J_z = 2.07$ meV. The precision of the DFT calculations in VASP was more than enough to assure the last digit. While the mean value of the exchange is very similar to the proposed J values in isotropic models, our calculations show that it is anisotropic, with an important amount of exchange anisotropy $J_y/J_x = 1.31$. It is important to note that the positive value of the Heisenberg exchange means a ferromagnetic coupling, in line with previous experimental results.^{14,19} The type and value of the exchange coupling in MPCs is strongly influeced by the stacking angle, hence by the Δ value.⁴⁷

The calculated single ion anisotropy is D = 0.65 meV, which is equivalent to ~ 7.5K, a value much lower than the estimations from experiments previously mentioned. Nevertheless, it is important to note that the calculated value agrees with earlier theoretical findings in which the preferred in plane magnetization direction was also identified.⁴¹ The easy plane anisotropy obtained is due to the spin-orbit interaction trying to align the spin with the orbital magnetic moment, this being the result of the orbital motions of the Fe electrons. Our results show an orbital magnetic moment greater in the molecular plane, with values of 0.118, 0.140, and 0.039 μ_B along the x, y, and z directions, respectively. However, these values are likely underestimated, as suggested by previous research.⁴³ DFT calculations tend to underestimate the orbital magnetic moment when electron correlation effects are important,^{51,52} and it is expected that the actual value of D is higher than in our calculations. Finally, the calculations showed than E is very small compared to the other parameters of the model, and consequently it will be disregarded from now on.

To this one-dimensional model for FePc chains we add interchain interactions J_{inter} that are expected to be one order of magnitude smaller than the intrachain ones, due to the large interchain Fe-Fe distance compared with the intrachain one.^{14,47} Although the DFT calculations were made for the particular geometry of the α + phase found in TF, we expect the model to account for the physics of other polymorphisms as well. Our results are summarized in table 1.

Table 1: DFT calculated parameters for the magnetic model of FePc TF α_+ phase.

α_+	J_x	J_y	J_z	D	Е
(meV)	1.77	2.31	2.07	0.65	0.04
(K)	20.5	26.8	24.0	7.5	0.5

Monte Carlo calculations.

Taking into account the ferromagnetic ground state of weakly coupled FePc chains, with individual molecules having spin S = 1, classical Monte Carlo is a suitable method to study its magnetic properties. All the Monte Carlo simulations presented in this work were performed on periodic FePc chains within a 3x3x1000 supercell. In such an arrange each spin, representing the Fe magnetic moment, interacts with 2 nearest neighbors within its chain and with 4 nearest neighbors belonging to different chains located along the directions of the x and y axes. The model Hamiltonian is the one described in Eq. 1, with the derived parameters: $J_{1x} = 1.76$ meV, $J_{1y} = 2.31$ meV, $J_{1z} = 2.07$ meV (equivalent to 20.5, 27 and 24 Kelvin, respectively), magnetic anisotropy D = 0.65 meV with the addition of interchain interactions of J_{inter} , which were shown to be relatively small but not negligible.^{14,47} The chosen value is $J_{inter} = 0.01$ meV, since for this value the transition temperature (i.e. the temperature at which there is a peak in susceptibility or specific heat curves, not shown) is of around 5 Kelvin, a value very similar to that reported in experiments.

Magnetization.

In magnetization experiments both in powders and thin films, the results showed that even at high fields of several Tesla, the magnetization per molecule did not saturate to the expected value for S = 1, that is $2g\mu_B$. In FePc powders, this was interpreted in terms of the herringbone structure (see above), due to the canting of the sublattices.¹⁹ On the other hand, in thin films, there is evidence that the structure is of the brickstack type,¹⁴ so that no canted two sublattice structure is present. All the same, the magnetization in thin films does not saturate at high fields. This suggests that another mechanism could be playing a role in this observed behaviour.

Concretely in Ref.,¹⁴ working with TF, it is shown that even at the lowest temperatures reached, of 2K:

- For the field in the molecular plane (Fig. 4 d, e, templated films), the magnetization did not saturate for fields as high as 7 Tesla, reaching $1.8\mu_B$ at this value of the field.
- For the field perpendicular to the molecular plane (Fig. 4 a, b, non-templated films), the magnetization is lower than that corresponding to the same value of B for B in the molecular plane ($M < 1\mu_B$ for B < 6 Tesla).

In the experiments in thin films, grains are formed, so that when the field is in the molecular plane, it can in principle form any angle with the molecular 'y' axis defined above. To simulate this, we have performed Monte Carlo simulations with the magnetic field B at varying angles with the y axis of the molecule, and we have averaged the magnetization, in the direction of the field, for all the directions of B between 0 and 90 degrees. This gives the results showed in table 2, all for a T = 2 Kelvin, the lowest reported in the experiments.

Table 2: Average magnetization (in Bohr magnetons) for different values of B_2
being the field in the molecular plane always. The Monte Carlo calculations
correspond to $T = 2 K$.

B (T)	1	2	3	4	5	6	7
$M_{avg}(\mu_B)$	1.30	1.39	1.47	1.54	1.61	1.66	1.73
M_{avg}/M_{sat}	0.65	0.70	0.73	0.77	0.80	0.83	0.86

The results are in very good agreement with those presented in Ref.¹⁴ For fields below 3 Tesla, the magnetization is below 1, 5 μ_B , i.e. 75% of the saturation vale, and for a field of

magnitude 7 Tesla, we obtain a magnetization of 1,73 $\mu_B \equiv 86\% M_{sat}$, close to the 1,8 μ_B reported in experiments that represented 83% of the saturation value. Thus, in the frame of our model, the magnetization does not saturate even at fields of 7 Tesla, due to the anisotropy of the exchange J.³

With our model, the non saturation of magnetization within the molecular plane can be explained as a consequence of the spatial anisotropy in the exchange J, since the difference between J_y and J_x is of ~ 0.5 meV. This can explain why the magnetization does not saturate with a field of several Tesla, since a field of 1 Tesla involves an energy of $g\mu_B B \sim 0.1$ meV for S = 1.

For a field perpendicular to the molecular plane, that is, in the z direction, the Monte Carlo results show that the magnetization is always lower, for any value of B, than the average magnetization for B in the molecular plane. Although the results show that $|J_x| < |J_z| < |J_y|$, with $J_x = 1.77$ meV, $J_z = 2.07$ meV and $J_y = 2.31$ meV, which would indicate that it is more favourable for the magnetic moment to move in the yz plane, if positive value of D = 0.65 meV is taken into account, the final result is that it is energetically more favorable for the magnetic moment to remain in the molecular plane. This explains the result mentioned above.

The previous results are in line with magnetization measurements in the xy and z direction,⁴³ and can also explain why in the non-templated films,¹⁴ in which the molecules are perpendicular to the substrate, when a field parallel to the substrate is applied, the magnetization is always lower than for the templated films, in which the field is always in the molecular plane. This is because in non-templated films, for some grains, the field is, or

³Within our model, saturation is indeed reached at much larger fields, and the non-saturation of the magnetization in FePc powders at B = 20 Tesla reported in Ref.¹⁹ has to be explained adding the canting of the FePc sublattices found in the herringbone phase.

almost is, perpendicular to the molecular plane, while for some others it is in the molecular plane, with intermediate situations for other grains, so that the average magnetization can be simulated as an average of the in plane magnetization with the out of plane one.

All in all, our model gives an explanation that can, at least partly, account for the reported results for the non-saturation of the magnetization in FePc thin films. It can be expected that this results also contribute to understand the experiments in FePc powders.

Magnetic Solitons

Ferromagnetic one dimensional systems have magnetic solitons as natural excitations above the ground state.^{14,53} Solitons possess special properties like stability, mobility without loosing their shape, and energy efficiency, making them promising candidates for various applications in the field of spintronics or information processing. For example, magnetic solitons have been proposed as a mechanism for remotely manipulating single qbits.⁵⁴ Besides, the density of magnetic solitons influences experimental measurements of specific heat,⁵⁵ neutron scattering experiments,⁵⁶ Mossbauer spectra⁵⁷ and dynamic structure factor.⁵⁸Several studies in similar model Hamiltonians 53,59,60 have found this type of excitations. They have also been reported in experimental studies of cuasi 1D compounds, being $CsNiF_3^{55,56}$ the paradigmatic ferromagnetic soliton bearing compound, and also others like quasi 1D antiferromagnets $Li_2Mn_{0.98}Fe_{0.02}F_5$ and $Na_2Mn_{0.98}Fe_{0.02}F_5$.⁵⁷ In relation to FePc chains, in Ref.²⁰ Mossbauer and a.c. susceptibility measurements, and in Ref.¹⁴ susceptibility measurements, were interpreted in terms of magnetic solitons, but with different models, or by means of an equation for the energy of the solitons derived from a renormalized Sine-Gordon theory.⁵³ Here, in the context of our first-principles derived model Hamiltonian, we study their existence, type and density, in particular as a function of temperature and magnetic field.

In figure 3 the three components of the spins along a segment of 200 sites of our model

is plotted, for T = 8K and a magnetic field of 0.25 Tesla in the 'y' direction. 2π solitons can be visualized. The observed solitons are predominantly of the xy type, i.e. the spins remain mostly in the plane of the molecule, but a certain amount of z component is also present. We have also made calculations with D 10 times higher, and checked that the number of solitons changes little but their z component decreases much further. In ferromagnetic isotropic Heisenberg models with single ion anisotropy, solitons are expected to be purely of the xy type for temperatures much lower than $T = (JD)^{1/2}/k_B$, which amounts to between 12 and 14 K for the parameters of this model, but ~ 40 K for D 10 times higher, and this is the reason why we observe a certain amount of z component in the solitons for the parameters of our model, but almost none for D enhanced by a factor of 10.

In order to calculate the density of magnetic solitons, the following quantitative criterion is established, following similar criteria established in previous works:^{59,61}

Figure 3: Snapshot of the spins along a selected segment of 200 sites (out of a total of 1000 sites per chain), representing the 1D arrangement of FePC molecules, for T = 8 K and a magnetic field of B = 0,25 Tesla. Several magnetic solitons, marked with circles, can be observed.

- 1. For a given temperature T we average the y components of all the sites and and obtain \bar{S}_y .
- 2. A soliton is counted if $\bar{S}_y > 0.4 \times S$ (in our case S=1) and at a certain site $i S_i^y < -0.4 \times \bar{S}_y$, and this remains valid for at least 3 more sites, i.e, the soliton width is larger than 3 sites. Thus we obtain n_s .

3. We then average the n_s values by repeating 2) every 10^6 MC steps out of a total of 10^9 steps.

Besides, for low fields, like in Fig. 3, we can roughly count the number of solitons per 100 sites visually, as is sketched in that figure. The criterion above gives the same number as the visual count. With this criterion, the density of magnetic solitons is plotted in Fig. 4, together with a fit by an Arrhenius equation.⁵⁹ We have tested that across the full range of temperatures and magnetic field strengths investigated, the statistical error associated with our results remained below 1.10^{-2} and decreases as n_s decreases.

 $n_s = (A/T)\exp(-E_s/T) \tag{6}$

Figure 4: Density of magnetic solitons as a function of temperature for several magnetic fields. The lines are fittings with eq. 6. The error bars are covered by the symbols.

We can see that the density of solitons increases exponentially as a function of temperature up to the transition temperature. From this temperature on, magnetic solitons decay abruptly to zero (not shown), and this occurs naturally because the magnetic order disappears. The fitting with the Arrhenius equation gives excellent results. Soliton energies are shown in Fig. 5 as a function of the magnetic field. For low magnetic fields, the energy is around 73 K, and grows linearly with the field. This energy is much higher than any of the J, and this is in line with what was found in antiferromagnetic Heisenberg models, where it was shown that a small amount of anisotropic exchange leads to the formation of solitons,⁵⁹ of energy much higher than J. The value obtained for the soliton energy has a very good agreement with what was obtained from Mossbauer/a.c. susceptibility experiments,^{17,20} i.e. 72 K with B = 0.08 Tesla. It is also in between the energy values from the classical domain wall theory $E_s = 2 \pi \sqrt{JD} \simeq 90K$ and the Sine-Gordon theory $E_s = 4 \sqrt{JD} \simeq 60K^{57}$ for an isotropic Heisenberg model with single ion anisotropy D, adopting for J the value of J_y for our model.

Figure 5: Energy of magnetic solitons as a function of magnetic field according to the fitting done with eq. 6. A linear regression is depicted by a dashed line.

Finally, in Fig. 6 we plot a colour map for the density of mangetic solitons as a function of magnetic field and temperature. It can be clearly observed how magnetic solitons are excited with temperature and magnetic field up to the transition to the paramagnetic phase. The magnetic field increases the transition temperature (for example at B = 1 Tesla the transition temperature is ~ 12K and for B = 4 Tesla is ~ 20K) and consequently solitons are excited up to higher temperatures as the field increases, but at the same time the soliton density reaches lower values. The highest solitons densities are reached for fields below 2 Tesla at temperatures between 8 and 12 K.

All in all, Monte Carlo simulations show the existence of magnetic solitons in the model

Figure 6: Density of magnetic solitons as a function of temperature for several magnetic fields.

proposed for α_+ FePc in thin films, which are thermally activated in the ferromagnetic phase and increase their energy with the application of a magnetic field, which renders them more difficult to be thermally excitated.

Conclusions.

In this work we have theoretically studied α_+ polymorphism of FePc Phthalocyanines that is found in thin films, consisting of quasi one dimensional chains of FePc molecules. By means of DFT calculations, after reproducing the structural properties of the phase, we have calculated the parameters of a Heisenberg model with single ion anisotropy, finding that due to the spin-orbit interaction the magnetic exchange interaction is anisotropic, i.e. that $J_x \neq J_y \neq J_z$, with $J_x = 1.77$ meV, $J_y = 2.31$ meV, and $J_z = 2.07$ meV. Calculations also show a single ion anisotropy D of 0.65 meV and negligible E. Adding to this one dimensional model a small interchain hopping, as estimated from experiments and theory,^{14,47} with classical Monte Carlo calculations we calculated the magnetization at low temperatures, finding that the non saturation found in thin films at fields up to 7 Tesla can be explained by the model. However, in FePc powders, the non-saturation of the magnetization extends to much higher fields, as a consequence of the canted structure of the herringbone arrangement. We have also found that our model is consistent with the existence of magnetic solitons in FePc TF. The solitons observed in MC calculations are of the 2π or double kink type. It is found that there is a non-negligible density of solitons even at zero magnetic field, and that the soliton energy for zero magnetic field is around 73 K, in line with Mossbauer and a.c. susceptibility experiments. Their energy increases linearly with magnetic field, and the thermal energy window in which they are exited is at higher temperatures as the field increases, but at the same time their density also decreases.

Conflicts of interest

There are no conflicts to declare.
