We have implemented noniterative triples corrections to the energy from coupled-cluster with single and double excitations (CCSD) within the 1-electron exact two-component (1eX2C) relativistic framework. The effectiveness of both the CCSD(T) and the completely renormalized (CR) CC(2,3) approaches are demonstrated by performing all-electron computations of the potential energy curves and spectroscopic constants of copper, silver, and gold dimers in their ground electronic states. Spin-orbit coupling effects captured via the 1eX2C framework are shown to be crucial for recovering the correct shape of the potential energy curves, and the correlation effects due to triples in these systems changes the dissociation energies by about 0.1–0.2 eV or about 4–7%. We also demonstrate that relativistic effects and basis set size and contraction scheme are significantly more important in Au₂ than in Ag₂ or Cu₂.

I. INTRODUCTION

Single-reference coupled-cluster (CC)^{1–4} theory has established itself as one of most successful approaches for high-accuracy *ab initio* electronic structure calculations. The exponential *ansatz* defining the ground-state CC wave function, combined with the connected^{5–8} and linked^{7,8} cluster theorems for the energy and wave function, respectively, lead to desirable properties such as size-extensivity and size-consistency of the ground-state CC energetics. Systematic truncation of the cluster operator leads to the well-known hierarchy of methodologies starting from the basic CC with singles and doubles (CCSD),^{9,10} CC with singles, doubles, and triples (CCSDT),^{11,12} CC with singles, doubles, triples, and quadruples (CCSDTQ),^{13–16} and so on. It is well known that the CCSD, CCSDT, CCSDTQ, etc. series provides a rapid convergence toward full configuration interaction (CI); the basic CCSD approach usually provides a qualitatively correct description of the system, and, with the inclusion of triples or quadruples, one can obtain a converged result relative to full CI.¹⁷

Although conceptually straightforward, the inclusion of higher-order cluster operators comes with a steep increase in the computational effort. Indeed, the computational effort of a CCSD calculation, using properly factorized implementation, scales as $n_o^2 n_u^4$, where n_o and n_u denote the numbers spin orbitals that are occupied and unoccupied in the reference configuration, respectively. This scaling increases to $n_o^3 n_u^5$ for CCSDT and $n_o^4 n_u^6$ for CCSDTQ, rendering such high-level CC calculations impractical for large molecules or basis sets. Thus, one of the primary goals in the development of new CC methodologies is the incorporation of correlation effects due to higher-than-doubly-excited cluster operators without incurring a significant increase in the computational cost. Efforts in this area have resulted in a variety of approaches, such

as the inclusion of selected parts of high-order cluster components in an iterative manner,^{18–22} non-iterative corrections to low-order CC energetics,^{23–34} and tensor decomposition techniques,^{35,36} to name a few examples. Among these options, non-iterative corrections have been a popular choice due to the relative simplicity of their implementation, especially if one is not interested in correcting the CC wave function itself.

Focusing on triples correlation effects, the CCSD(T)²³ approximation to CCSDT has been hailed as the “gold standard” due to its ability to capture a significant part of the desired correlations, especially near equilibrium geometries. However, CCSD(T) was derived using many-body perturbation theory (MBPT) arguments and, thus, it may give rise to an unphysical description of the system, such as a bump in the potential energy curve (PEC) along bond dissociation coordinates, especially when restricted Hartree–Fock (HF) references are used. Various non-iterative triples corrections aim to eliminate this unphysical behavior while faithfully recovering a CCSDT-level description of the systems of interest, and the completely renormalized (CR) CC(2,3)^{27–31} methodology stands out as one of the most successful options. Indeed, CR-CC(2,3) is able to correctly describe PECs where CCSD(T) overcorrelates in the dissociation limit, and it usually outperforms CCSD(T) in reproducing the full CCSDT description for many chemically interesting situations, ranging from the homolytic dissociation of alkaline earth dimers^{37,38} to the challenging description of singlet–triplet gap in biradical species.³⁰ The CR-CC(2,3) method is part of a more general non-iterative correction scheme called CC(*P*;*Q*) introduced in Refs. 32–34, which accounts for arbitrary truncation of the cluster operator. While not the focus of the present work, it is worth noting that these approaches can be extended to treat electronically excited states^{28,39–41} via the equation-of-motion (EOM)^{42,43} framework.

Aside from high-order correlation effects, accurate descriptions of spin-orbit coupling, core-excited states, and molecules containing heavy elements require the consideration of relativistic effects. The exact two-component (X2C)^{44–64} approach has gained popularity owing to its ability

^{a)}Electronic mail: xqli@uw.edu

^{b)}Electronic mail: adeprince@fsu.edu

to downfold relativistic effects from the full four-component (4c) Hamiltonian into a more computationally manageable two-component (2c) framework. Furthermore, while 4c relativistic calculations require the use of uncontracted basis sets to avoid variational collapse or prolapse,^{65–68} X2C benefits from having the ability to use re-contracted basis set after the 4c→2c transformation, further reducing the computational cost.⁶⁹ For quantum chemistry applications, it is commonplace to use the X2C framework at the mean-field level and then employ the no-virtual-pair approximation^{70–74} in post-HF calculations such that one only has to account for electron-electron correlation effects, without noticeable loss of accuracy. Indeed, the X2C Hamiltonian has been successfully applied to heavy elements, core-excited phenomena, and core or valence spectral splitting when combined with CC approaches or other methods that include electronic correlations.^{62–64,75–87} We also note that there are a number of efforts in incorporating relativity in CC calculations through approaches other than X2C.^{88–102}

Focusing on X2C-based single-reference CC calculations beyond the CCSD level, several studies have employed spin-free and spin-orbit coupling versions of X2C-CCSD(T) (see, *e.g.*, Refs. 78, 79, 83, and 85), but we are not aware of any that combined the X2C relativistic treatment with CR-CC(2,3). In this paper, we present our implementation of CCSD(T) and CR-CC(2,3) within the mean-field X2C framework, with spin-orbit coupling effects. The coinage metal dimers Cu₂, Ag₂, and Au₂ serve as test systems for our CCSD, CCSD(T), and CR-CC(2,3) calculations. Prior experimental and theoretical investigations of these systems have yielded reliable energetics and spectroscopic parameters,^{98,103–133} and it has been shown, especially for the heavier dimers, that relativistic effects can significantly change the description of the PECs. To the best of our knowledge, prior relativistic CCSD, CCSD(T), and/or CR-CC(2,3) calculations of these systems relied on the use of effective core potentials (ECPs) and/or correlating only the valence and semicore electrons. As such, the present work offers the first all-electron X2C-CC calculations on these systems. Furthermore, we also study the effects of basis set truncation level and contraction scheme on the results of all-electron X2C-CC computations, highlighting the deficiencies of relativistic basis sets not specifically optimized for all-electron calculations with spin-orbit coupling, which has not received much attention in the previous works relying on frozen-core approximations or using ECPs.

The remaining parts of this paper are organized as follows. In Section II, we provide a short summary of the X2C formalism, CC theory, and the derivation of CR-CC(2,3) and its relationship with the CCSD(T) approach. We provide the relevant details of our computational protocols for obtaining the PECs of the coinage metal dimers in Section III. We discuss our findings in Section IV, focusing on the impact of triples correlation effects, the contrast between relativistic and non-relativistic calculations, and the effects of basis set size and contraction scheme, and we provide a concluding summary in Section V.

II. THEORY

A. Exact two-component transformation

The details of the X2C transformation employed in this work have been described elsewhere (see, Ref. 56, for example), so we provide here a summary of the relevant elements. Throughout this work, we are concerned with the electronic Hamiltonian, which in second quantization can be expressed as

$$\hat{H} = h_p^q \hat{a}^p \hat{a}_q + \frac{1}{4} g_{pq}^{rs} \hat{a}^p \hat{a}^q \hat{a}_s \hat{a}_r. \quad (1)$$

In Eq. (1), h_p^q and g_{pq}^{rs} are (antisymmetrized) matrix elements of the one- and two-electron parts of the Hamiltonian and \hat{a}_p and $\hat{a}^p \equiv \hat{a}_p^\dagger$ are the fermionic annihilation and creation operator associated with the spin-orbital label p . In this paper, we use the Einstein convention where repeated lower and upper indices imply summation. In the X2C framework, we begin with the 4c relativistic Dirac Hamiltonian for the electrons in a restricted-kinetic-balanced condition,^{134–136}

$$\hat{H}^{4c} = \begin{pmatrix} V\mathbf{I} & T\mathbf{I} \\ T\mathbf{I} & \mathbf{W} - T\mathbf{I} \end{pmatrix}. \quad (2)$$

In Eq. (2), V is the scalar potential, \mathbf{I} is the 2×2 identity matrix, T is the kinetic energy, and

$$\mathbf{W} = \frac{1}{4m^2c^2} (\boldsymbol{\sigma} \cdot \mathbf{p}) V (\boldsymbol{\sigma} \cdot \mathbf{p}), \quad (3)$$

where m is the mass of an electron, c is the speed of light, $\boldsymbol{\sigma}$ is the vector of Pauli matrices, and \mathbf{p} is the linear momentum operator. The eigenstates of this Hamiltonian can be expressed as

$$\Psi^{4c} = \begin{pmatrix} \Psi_L \\ \Psi_S \end{pmatrix}, \quad (4)$$

in which Ψ_L and Ψ_S are the large and small components, respectively, that can be further broken down into their α and β spin components. Solving this eigenvalue problem yields positive- and negative-energy states, the former of which are of interest in the electronic structure calculations. To isolate the positive-energy states, one may perform a unitary transformation

$$\mathbf{U}^\dagger \hat{H}^{4c} \mathbf{U} = \begin{pmatrix} \hat{H}^+ & \mathbf{0} \\ \mathbf{0} & \hat{H}^- \end{pmatrix}, \quad \mathbf{U}^\dagger \Psi^{4c} = \begin{pmatrix} \Psi^{2c} \\ \mathbf{0} \end{pmatrix}, \quad (5)$$

where \hat{H}^\pm describe the positive- and negative-energy states and Ψ^{2c} are the 2c eigenstates of these Hamiltonians. In this work, the 4c→2c transformation described in Eq. (5) is applied to the one-electron part of the Hamiltonian, while the two-electron part is treated nonrelativistically. In this approximation, which is usually denoted as 1eX2C, we applied an empirical screened-nuclei spin-orbit (SNSO)^{137,138} scaling factor to the one-body integrals to mimic the spin-orbit coupling effects on the two-body part of the electronic Hamiltonian. Additionally, as already mentioned in Section I, the X2C transformation is done at the mean-field (*i.e.*, HF) level and we employ the no-virtual-pair approximation in the correlated calculations.

B. Coupled-cluster theory

The ground-state CC wave function for an N -electron system is given by the exponential *ansatz*

$$|\Psi\rangle = e^{\hat{T}} |\Phi\rangle, \quad (6)$$

where \hat{T} is the cluster operator and $|\Phi\rangle$ is a reference Slater determinant (here, a HF determinant). The cluster operator is expanded by excitation order as

$$\hat{T} = \sum_{n=1}^N \hat{T}_n, \quad \hat{T}_n = t_{a_1 \dots a_n}^{i_1 \dots i_n} E_{i_1 \dots i_n}^{a_1 \dots a_n}, \quad (7)$$

where $t_{a_1 \dots a_n}^{i_1 \dots i_n}$ is a cluster amplitude and $E_{i_1 \dots i_n}^{a_1 \dots a_n} = \prod_k \hat{a}^{a_k} \hat{a}_{i_k}$ is the usual n -body particle–hole excitation operator, which generates the manifold of excited determinants $|\Phi_{i_1 \dots i_n}^{a_1 \dots a_n}\rangle = E_{i_1 \dots i_n}^{a_1 \dots a_n} |\Phi\rangle$. We use the indices i_1, i_2, \dots (i, j, \dots) and a_1, a_2, \dots (a, b, \dots) to designate the spin orbitals that are occupied and unoccupied, respectively, in the reference determinant. The cluster amplitudes are obtained by solving a system of non-linear, energy-independent equations

$$\langle \Phi_{i_1 \dots i_n}^{a_1 \dots a_n} | \bar{H} | \Phi \rangle = 0 \quad \forall |\Phi_{i_1 \dots i_n}^{a_1 \dots a_n}\rangle, \quad n = 1, \dots, N, \quad (8)$$

in which $\bar{H} = e^{-\hat{T}} \hat{H} e^{\hat{T}}$ is the similarity-transformed Hamiltonian, and the ground-state energy is computed as the expectation value

$$E^{(\text{CC})} = \langle \Phi | \bar{H} | \Phi \rangle. \quad (9)$$

Due to the non-hermiticity of \bar{H} , if properties other than energies are desired, one also needs to solve the left-hand CC problem. The left-hand CC wave function is parameterized as

$$\langle \tilde{\Psi} | = \langle \Phi | (\mathbf{1} + \hat{\Lambda}) e^{-\hat{T}}, \quad (10)$$

where $\hat{\Lambda}$ is the many-body de-excitation operator

$$\hat{\Lambda} = \sum_{n=1}^N \hat{\Lambda}_n, \quad \hat{\Lambda}_n = \lambda_{i_1 \dots i_n}^{a_1 \dots a_n} (E_{i_1 \dots i_n}^{a_1 \dots a_n})^\dagger. \quad (11)$$

One obtains the $\lambda_{i_1 \dots i_n}^{a_1 \dots a_n}$ amplitudes by solving a linear system of equations

$$\begin{aligned} \langle \Phi | (\mathbf{1} + \hat{\Lambda}) (\bar{H} - \mathbf{1} E^{(\text{CC})}) | \Phi_{i_1 \dots i_n}^{a_1 \dots a_n} \rangle &= 0 \\ \forall |\Phi_{i_1 \dots i_n}^{a_1 \dots a_n}\rangle, \quad n = 1, \dots, N, \end{aligned} \quad (12)$$

It is worth mentioning that the single-reference CC formalism as described above is equivalent to the full CI methodology. However, in practice, the many-body expansion of \hat{T} and $\hat{\Lambda}$ along with the corresponding projection spaces used in Eqs. (8) and (12) are truncated at a computationally tractable level (much lower than N), giving rise to the usual CCSD, CCSDT, etc. hierarchy. As mentioned in Sec. I, it is well known that CCSD is often not sufficient to produce quantitatively accurate results and, thus, one of the main objectives in the field is the incorporation of correlation effects due to higher-than-doubly excited clusters without incurring significant computational costs.

C. Non-iterative triples corrections to CCSD energetics

In this work, we focus on the CR-CC(2,3) correction to CCSD energetics. Let us recall that the CR-CC approaches arise from the biorthogonal moment expansion derived via the method-of-moments of CC equations (MMCC)^{30,32,40,139–145} framework, which avoids using MBPT analysis in incorporating the higher-order corrections to lower-order CC energies. The derivation of CR-CC(2,3) working equations from the asymmetric energy expression has been discussed in great detail in the literature (see, *e.g.*, Refs. 27–30), and we only provide a summary in this subsection. In a CR-CC(2,3) calculation, one begins by solving the right- and left-hand CCSD problems by setting $\hat{T} = \hat{T}_1 + \hat{T}_2$ and $\hat{\Lambda} = \hat{\Lambda}_1 + \hat{\Lambda}_2$ and solving Eqs. (8) and (12) in the space of singly and doubly substituted determinants. Subsequently, the CCSD energy is corrected using the CR-CC(2,3) moment expansion

$$\delta(2,3) = \frac{1}{36} \ell_{ijk}^{abc}(2) \mathfrak{M}_{abc}^{ijk}(2). \quad (13)$$

The moments $\mathfrak{M}_{abc}^{ijk}(2)$ are defined as the projections of the Schrödinger equation containing the CCSD wave function onto triply excited determinants,

$$\mathfrak{M}_{abc}^{ijk}(2) = \langle \Phi_{ijk}^{abc} | \bar{H}^{(\text{CCSD})} | \Phi \rangle, \quad (14)$$

where $\bar{H}^{(\text{CCSD})} = e^{-\hat{T}_1 - \hat{T}_2} \hat{H} e^{\hat{T}_1 + \hat{T}_2}$. Note that the triples moments in Eq. (14) are non-zero because these projections are not part of the CCSD amplitude equations. The $\ell_{ijk}^{abc}(2)$ amplitudes entering Eq. (13) are defined as

$$\ell_{ijk}^{abc}(2) = \langle \Phi | (\hat{\Lambda}_1 + \hat{\Lambda}_2) \bar{H}^{(\text{CCSD})} | \Phi_{ijk}^{abc} \rangle / D_{ijk}^{abc}, \quad (15)$$

where we have introduced a quasi-perturbative denominator D_{ijk}^{abc} , which is given by the Epstein–Nesbet-like expression

$$D_{ijk}^{abc} = E^{(\text{CCSD})} - \langle \Phi_{ijk}^{abc} | \bar{H}^{(\text{CCSD})} | \Phi_{ijk}^{abc} \rangle. \quad (16)$$

The above set of equations describe the most complete variant of CR-CC(2,3), usually denoted as CR-CC(2,3)_D, which includes up to the three-body component of $\bar{H}^{(\text{CCSD})}$ in Eq. (16). One could introduce a simplification by including only the one-body component or the one- and two-body parts of $\bar{H}^{(\text{CCSD})}$ in the denominator, resulting in the CR-CC(2,3)_B and CR-CC(2,3)_C variants, respectively, or even go further and replace the Epstein–Nesbet-like expression in Eq. (16) by its Møller–Plesset variant involving orbital energy differences, to obtain the simplest CR-CC(2,3)_A approach (which is equivalent to CCSD(2)_T of Ref. 26). As has been discussed and demonstrated extensively,^{27–31} the most complete D variant usually outperforms its A–C approximate versions. However, due to the use of Epstein–Nesbet denominator, CR-CC(2,3)_D is not invariant with respect to rotations of degenerate orbitals.³⁰ In fact, only the A and B versions of CR-CC(2,3) are orbital invariant, because these approaches use only the (effective) one-body part of the Hamiltonian in the denominator. One could avoid this issue by using the $\ell_{ijk}^{abc}(2)$

amplitudes involving degenerate orbitals that are obtained through solving a linear system of equation in the appropriate subspace (see, *e.g.*, Ref. 146 for more details). The arbitrary mixing of the spatial parts of degenerate orbitals can be cleaned up through the use of point group or double point group symmetry, but issues may still persist regarding α and β spin mixing that can occur in relativistic calculations with spin-orbit coupling effects. Nevertheless, in this work, we opt to implement all variants of CR-CC(2,3) following the above description to ensure reproducibility with existing CR-CC(2,3) implementations, assuming that the exact same set of molecular orbitals are used.

Before moving on, it is worth mentioning that the CCSD(T) methodology can be understood from the lens of CR-CC(2,3) by making several modifications. Specifically, one uses a simpler form of Eq. (13), in which one makes the approximations

$$\mathfrak{M}_{abc}^{ijk}(2) \approx \langle \Phi_{ijk}^{abc} | (\hat{V}_N \hat{T}_2)_C | \Phi \rangle \quad (17)$$

and

$$\ell_{ijk}^{abc}(2) \approx \langle \Phi | (\hat{V}_N \hat{T}_1)_{DC}^\dagger + (\hat{V}_N \hat{T}_2)_C^\dagger | \Phi_{ijk}^{abc} \rangle / D_{ijk}^{abc}. \quad (18)$$

Here, \hat{V}_N is the normal-ordered two-body part of the Hamiltonian, the subscripts C and DC refer to connected and disconnected diagrams, respectively, and we employ the Møller–Plesset form of D_{ijk}^{abc} in Eq. (18).

III. COMPUTATIONAL DETAILS

Our objectives in this paper are to demonstrate the improvements that CCSD(T) and CR-CC(2,3) deliver on top of CCSD energetics in the context of relativistic calculations, as well as to highlight the sensitivity of all-electron correlated calculations to the choice of basis set contraction scheme and size. To that end, we computed the ground-state PECs of Cu₂, Ag₂, and Au₂ using the CCSD, CCSD(T), and CR-CC(2,3) (variants A–D) approaches. In particular, we focus on the dissociation energy (D_e), equilibrium bond distance (R_e), and fundamental vibrational frequency (ω_e) characterizing the PECs obtained using the ANO-RCC-VDZP basis set.¹⁴⁷ In addition to the different levels of electronic correlation treatment, we also examine how relativistic effects modify the PECs by comparing the results based on generalized HF (GHF), spin-free 1eX2C-HF (SF-1eX2C-HF), and 1eX2C-HF reference functions. In the case of the 1eX2C-HF calculations, we utilized the row-dependent SNSO scaling factors of Ref. 138 that were parameterized using the full 4c Dirac–Coulomb–Breit Hamiltonian.

Our CC implementations are based on the Kramers-unrestricted formalism, and, thus, are separable at the dissociation asymptote. Nevertheless, to provide a more complete picture of how the different triples corrections behave, for each dimer we computed the potentials that follow both the Kramers-unrestricted/“spin-broken” [*i.e.*, $\langle \hat{S}^2 \rangle = 1$ and $E(X_2) = 2E(X)$ at the dissociation limit] as well as Kramers-restricted/“spin-pure” (*i.e.*, $\langle \hat{S}^2 \rangle = 0$ throughout the entire

curve) reference PECs. The potential curves are computed at the points on the grid defined in Table I. Subsequently, we fitted each PEC at the lowest-energy point in the grid and the two points adjacent to it to a 2nd-order polynomial, and use the resulting information to obtain our D_e , R_e , and ω_e estimates.

TABLE I. Grids of internuclear distances (in Å) employed in the PEC calculations of Cu₂, Ag₂, and Au₂.

Step size	Cu ₂	Ag ₂	Au ₂
0.10	1.70–2.50	2.00–2.90	1.50–2.90
0.50	3.00–5.00	3.00–5.00	3.00–5.00
1.00	6.00–8.00	6.00–8.00	6.00–8.00

In addition to the PEC studies using the ANO-RCC-VDZP basis set, we investigate the convergence of our CC calculations with respect to the basis set size by using the ANO-RCC-VTZP, ANO-RCC-VQZP, and ANO-RCC sets. In the case of gold dimer, we also performed additional computations using the full ANO-RCC set with an extra *i*-type primitive (exponent = 15.1665360) obtained from the “dyall.ae4z” basis set.^{148,149} We also compared the convergence of the all-electron CC calculations using the ANO-RCC series with the x2c-SVPall-2c, x2c-TZVPall-2c, x2c-TZVPPall-2c, and x2c-QZVPPall-2c basis sets,^{150,151} which were optimized in all-electron 1eX2C-HF calculations including spin-orbit coupling effects. All of these calculations were performed at the grid point closest to the equilibrium bond distance found in the 1eX2C-CCSD/ANO-RCC-VDZP calculations for each of the dimers.

All of the electronic structure calculations reported in this work were performed using a development branch of the Chronus Quantum software package.¹⁵² All basis sets were extracted from the Basis Set Exchange.^{153–155} The CCSD(T) and CR-CC(2,3) working equations were derived with the help of the p[†]q automated code generator¹⁵⁶ and implemented using the TiledArray¹⁵⁷ high-performance tensor arithmetic framework. The resulting code was benchmarked numerically against the CC routines^{39,158} in GAMESS version 2022 R2.^{159,160} In the relativistic calculations, the speed of light $c = 137.035999074$ a.u. was used.

IV. RESULTS AND DISCUSSION

A. Cu₂

We begin our discussion with the smallest system in our test set, the copper dimer (in particular, the ⁶³Cu₂ isotopolog). In terms of the electronic structure, we are interested in the ground ¹Σ_g⁺ state that dissociates into two Cu atoms, each in a ²S ([Ar] 3d¹⁰4s¹) configuration. There have been extensive experimental and theoretical investigations of the ground electronic state of this molecule (see Refs. 103–115 for selected examples). The latest experimental investigation,¹¹⁴ aided with CCSD(T) and multi-reference CI calculations, yielded a dissociation energy estimate of $D_e = 16,270$ cm⁻¹ (2.02

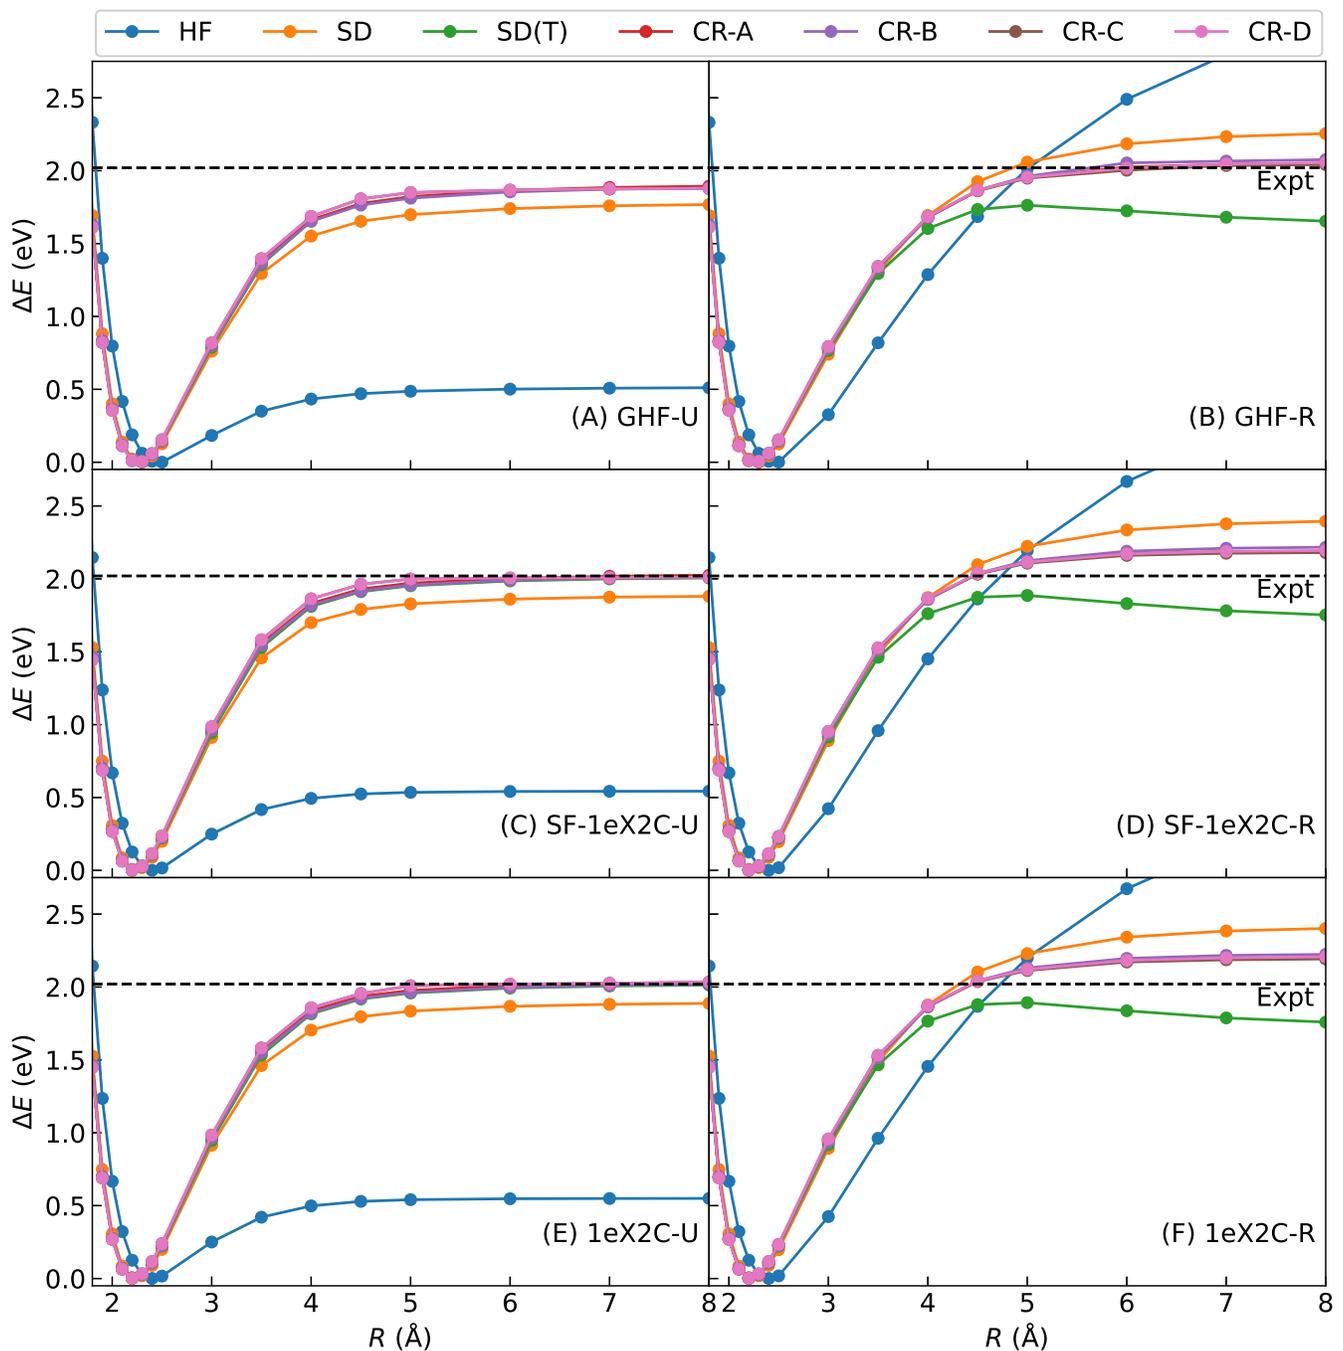

FIG. 1. The PECs of Cu_2 obtained in this work using the ANO-RCC-VDZP basis set. The U and R labels indicate Kramers-unrestricted and restricted reference curves, respectively. Each PEC is shifted relative to the energy at R_e (cf. Table III).

eV), Cu–Cu equilibrium distance of $R_e = 2.218 \text{ \AA}$, and the harmonic frequency of $\omega_e = 266.487 \text{ cm}^{-1}$, all of which can be considered to be converged results. Here, our goal is to assess different relativistic schemes and electronic correlation treatments, as compared to these existing results; our data are summarized in Fig. 1 and Table II.

We begin by considering the PECs shown in Fig. 1 and the corresponding D_e values in Table II. From Fig. 1, we can make

a few interesting observations regarding the different relativistic and electron correlation treatments, as well as whether the PECs follow the Kramers-unrestricted or restricted solutions. First of all, the HF PECs significantly underbind and overbind the Cu_2 dimer in the Kramers-unrestricted and restricted cases, respectively, regardless of the specific relativistic treatment, which is not surprising. In general, neither spin-free nor spin-orbit coupling relativistic effects have much im-

^b Ref. 114.

pect on the Kramers-unrestricted HF potential wells, changing the dissociation energies by no more than 0.03 eV. These effects are somewhat more significant in the Kramers-restricted case, deepening the HF well by about 0.2 eV compared to the nonrelativistic case.

The differences between PECs calculated using correlated approaches are more noticeable. Beginning with CCSD, in the non-relativistic regime [Fig. 1(A) and (B)], we observe a significant improvement over the underlying HF PECs, with dissociation asymptotes that are much closer to the experimentally determined values. However, Kramers-unrestricted GHF-CCSD still underbinds the Cu_2 molecule by about 0.3 eV, whereas its restricted counterpart overbinds Cu_2 by ~ 0.2 eV. The SF-1eX2C and 1eX2C relativistic frameworks offer a slight improvement in the Kramers-unrestricted case, reducing the CCSD error to about -0.2 eV as seen on panels (C) and (E) of Fig. 1, but they actually worsen the Kramers-restricted GHF-CCSD results by ~ 0.1 eV. Thus, for Cu_2 , relativity changes the PEC by inducing a stronger Cu–Cu bond as shown by the increase in D_e , regardless of the reference behavior.

The triples correction significantly changes the overall picture. On the Kramers-unrestricted side, we see an interesting pattern where all of the triples corrections examined in this work have similar impacts on the ground-state PECs for Cu_2 ; all triples corrections deepen the respective reference CCSD potential wells by about 0.1 eV. In contrast, the Kramers-restricted CCSD(T) and CR-CC(2,3) PECs behave differently. The CCSD(T) PECs show the well-known unphysical bumps that accompany the overcorrelation of the dissociation asymptote, regardless of the relativistic treatment used. On the other hand, all variants of CR-CC(2,3) shown in Fig. 1(B), (D), and (F) are numerically stable and exhibit no artificial bumps along the bond dissociation coordinate. The fact that the Kramers-restricted GHF-CR-CC(2,3) PECs in Fig. 1(B) accurately predicts the experimental D_e value is a coincidence; once the missing relativistic effects are added [panels (D) and (F)], the CR-CC(2,3) curves overestimate the experimentally determined D_e by about 0.1 eV. This surprising accuracy of Kramers-restricted GHF-CR-CC(2,3) suggests that errors from other effects, such as basis set size, may be responsible for a fortuitous cancellation of error. We will return to this

issue in Subsection IV D below.

At this point, it is worth discussing how the Kramers-unrestricted and restricted PECs can help us understand the convergence of truncated CC methods toward the exact full CI limit. Because full CI is the exact solution within a given basis set, the Kramers-restricted or unrestricted HF reference must give rise to the same full CI solution. In Fig. 1, we see that by increasing the level of electron correlation treatment, the Kramers-unrestricted and restricted potential well becomes deeper and shallower, respectively. Thus, we can use the difference between the Kramers-unrestricted and restricted energetics as an uncertainty estimate with respect to the full CI energetics. For example, in all panels, the Kramers-unrestricted GHF-, SF-1eX2C-, and 1eX2C-CCSD dissociation energies differ from their Kramers-restricted counterparts by about 0.5 eV, which indicates that CCSD is still far from converged in terms of electronic correlation effects. In contrast, the difference between the Kramers-unrestricted and restricted CR-CC(2,3) dissociation energies are on the order of 0.1–0.2 eV, which represents a massive 60%–80% reduction in uncertainty relative to their CCSD counterparts and thus much better convergence toward the full CI limit. The CCSD(T) approach is unfortunately not amenable to such an analysis due to the artificial bump in the 4–5 Å region for the Kramers-restricted Cu_2 PECs.

Let us now take a closer look at the other spectroscopic parameters of Cu_2 reported in Table II. Focusing on the equilibrium bond distances, we see that CCSD(T) and all CR-CC(2,3) variants shorten the CCSD R_e estimates by about 0.02 Å, regardless of the level of mean-field relativistic treatment. The inclusion of spin-free and spin-orbital relativistic effects is more important, shortening the equilibrium bond length by about 0.4 Å when compared to the non-relativistic data. This pattern also follows the expected relativistic contraction when comparing non-relativistic and relativistic calculations. Note, however, that the SF-1eX2C and 1eX2C calculations produced practically identical bond lengths, corroborating our qualitative observation of the PECs reported in Fig. 1, which, as in the energetics analysis, indicates that spin-orbit coupling effects are minimal for Cu_2 . We also see a similar pattern in the harmonic frequencies; the spin-free and spin-orbit-coupled 1eX2C calculations reduces the magnitude of errors

relative to experiment obtained in the non-relativistic CC data, from 30–40 cm^{-1} to about 12–16 cm^{-1} on average. In analogy to the equilibrium bond distance, the triples correlation effects are much less pronounced than the relativistic effects, changing the harmonic frequency by only $\sim 4 \text{ cm}^{-1}$. Interestingly, the C and D variants of 1eX2C-CR-CC(2,3) worsen the ω_e estimate compared to 1eX2C-CCSD and the A and B versions by about 5 cm^{-1} (~ 23 microhartree). This behavior could be related to the orbital invariance issues with CR-CC(2,3)_C and CR-CC(2,3)_D.

B. Ag₂

We proceed to the next dimer in the series, Ag₂, focusing on the $^{107}\text{Ag}_2$ isotopolog. As above, we are interested in the ground $^1\Sigma_g^+$ state, which, at the dissociation limit, separates into two Ag atoms with ^2S ([Kr] $4d^{10}5s^1$) electronic configurations. The ground state of this dimer, like that of Cu₂, has been the subject of extensive experimental and theoretical investigations (see, e.g., Refs. 107, 110, 111, 115–123). Note that the majority of the available experimental investigation correspond to the mixed $^{107,109}\text{Ag}_2$ dimer, which is about twice as abundant as the $^{107}\text{Ag}_2$ one. Nevertheless, due to the very small (i.e., $< 1\%$) difference in the reduced masses of the two isotopologs, the impact on the numerical data of interest is negligible. The experimentally derived spectroscopic constants for Ag₂ are D_e of about 1.66 eV ($D_0 = 1.65$ eV plus a zero-point energy of about 96 cm^{-1} or 0.01 eV),^{107,116} $R_e = 2.5303 \text{ \AA}$,¹¹⁹ and $\omega_e = 192.4 \text{ cm}^{-1}$.¹¹⁶ Given that the nuclear charge and mass of the ^{107}Ag isotope are 62% and 70% higher than those of ^{63}Cu , we can anticipate that relativistic effects will play a more important role in the overall energetics of Ag₂. Indeed, our data, which are summarized in Fig. 2 and Table III, are consistent with this expectation.

Figure 2 depicts ground-state PECs of Ag₂ computed using the ANO-RCC-VDZP basis set with varying levels of relativistic and electron correlation effects, while following either Kramers-unrestricted or restricted reference curves. We note the following differences between the PECs generated for Ag₂ and those for Cu₂ that we discussed above. First, consider the exaggerated attractive interaction in the GHF-based curves for Ag₂ shown in Fig. 2(A) and (B). While this behavior is expected for the Kramers-restricted PEC, it is surprising to see that remnants of long-range interactions remain in the Kramers-unrestricted case, even after electronic correlation effects are included. Despite this peculiar behavior, we note that each of the Kramers-unrestricted PECs are still properly separable, i.e., the energy at large Ag–Ag separations (100 \AA) is twice the energy of an Ag atom. The unexpected overbinding of GHF-based CCSD/CCSD(T)/CR-CC(2,3) PECs may be due to use of the ANO-RCC-VDZP basis set for non-relativistic all-electron correlated calculations. This basis set was designed for modeling valence and semicore correlations with spin-free relativistic treatments. Second, it is noteworthy that the restricted GHF-CCSD(T) curve [Fig. 2(B)] does not show the expected unphysical hump, at least up to $R = 8.00 \text{ \AA}$. The lack of this feature could be attributable to the severe

overbinding observed in the non-relativistic PECs.

The inclusion of relativistic effects leads to a dramatic improvement in the description of the ground-state PEC of Ag₂. Spin-free relativistic effects [SF-1eX2C, Fig. 2(C)] eliminate the artificial long-range interaction seen in the Kramers-unrestricted GHF PECs in Fig. 2(A). The quality of the Kramers-unrestricted SF-1eX2C-based PECs of Ag₂ in Fig. 2(C) is comparable to that of their Cu₂ counterparts shown in Fig. 1(C); the D_e derived from Kramers-unrestricted SF-1eX2C-CCSD differs from the experimental value by only ~ 0.1 eV, while Kramers-unrestricted SF-1eX2C-CCSD(T) and CR-CC(2,3) provide consistent results that reduce this error by an order of magnitude. This situation contrasts with that for the Kramers-restricted case, the data for which are reported in Fig. 2(D). Here, we find appreciable differences between the PECs obtained using the four SF-1eX2C-CR-CC(2,3) variants, especially in the $R = 5.00\text{--}8.00 \text{ \AA}$ region. The B variant leads to the largest deviation from the experimental D_e data, followed by variant A, while CR-CC(2,3)_C and D produce slightly better D_e estimates (cf. the SF-1eX2C-based dissociation energy values in Table III). These observations are consistent with the well-known behavior of the different denominators in the CR-CC framework relying on restricted and restricted open-shell HF references (see, e.g., Ref. 30).

Due to the larger size of Ag₂ compared to Cu₂, spin-orbit coupling effects are also more pronounced in this case [Fig. 2(E) and (F)]. Indeed, the 1eX2C PECs for Ag₂ show a noticeable difference from their SF-1eX2C analogs in panels (C) and (D), unlike the practically identical SF-1eX2C and 1eX2C PECs obtained for Cu₂ (Fig. 1). In particular, for each of the methods shown in Table III, the 1eX2C-based D_e estimates are about 0.07–0.08 eV higher than their SF-1eX2C counterparts in both the restricted and unrestricted cases. Even though spin-orbit coupling effects are minimal for the $^1\Sigma_g^+$ state and the dissociated $^2\text{S} + ^2\text{S}$ configurations, they still impact the HF orbital energies and spatial splittings,^{150,161} as well as the subsequent CC energetics. Despite the overall change in the PECs upon the inclusion of spin-orbit coupling, it is encouraging to see that the triples correction afforded by CCSD(T) and all variants of CR-CC(2,3) behave consistently as in the SF-1eX2C case; they deepen the underlying CCSD potential well by about 0.1 eV.

As in the case of Cu₂, we can use the difference between Kramers-unrestricted and restricted dissociation asymptotes of Ag₂ as a proxy for the completeness of the correlation treatment in CCSD and CR-CC(2,3). Here, the CCSD asymptotes differ by more than 0.7 eV in both SF-1eX2C and 1eX2C cases, which is almost 50% of the experimentally derived value of D_e itself. In contrast, the non-iterative triples correction significantly reduce this error bar. In the case of (SF-)1eX2C-CR-CC(2,3) variants A, C, and D, the difference between Kramers-unrestricted and restricted D_e estimate is only 0.15–0.17 eV, or about 9%–10% of the experimentally derived dissociation energy. This difference is slightly larger in the case of the CR-CC(2,3)_B approach (0.25 eV, see Table III), which is still a significant improvement over CCSD. As in the case of Cu₂, we cannot apply a similar analysis for

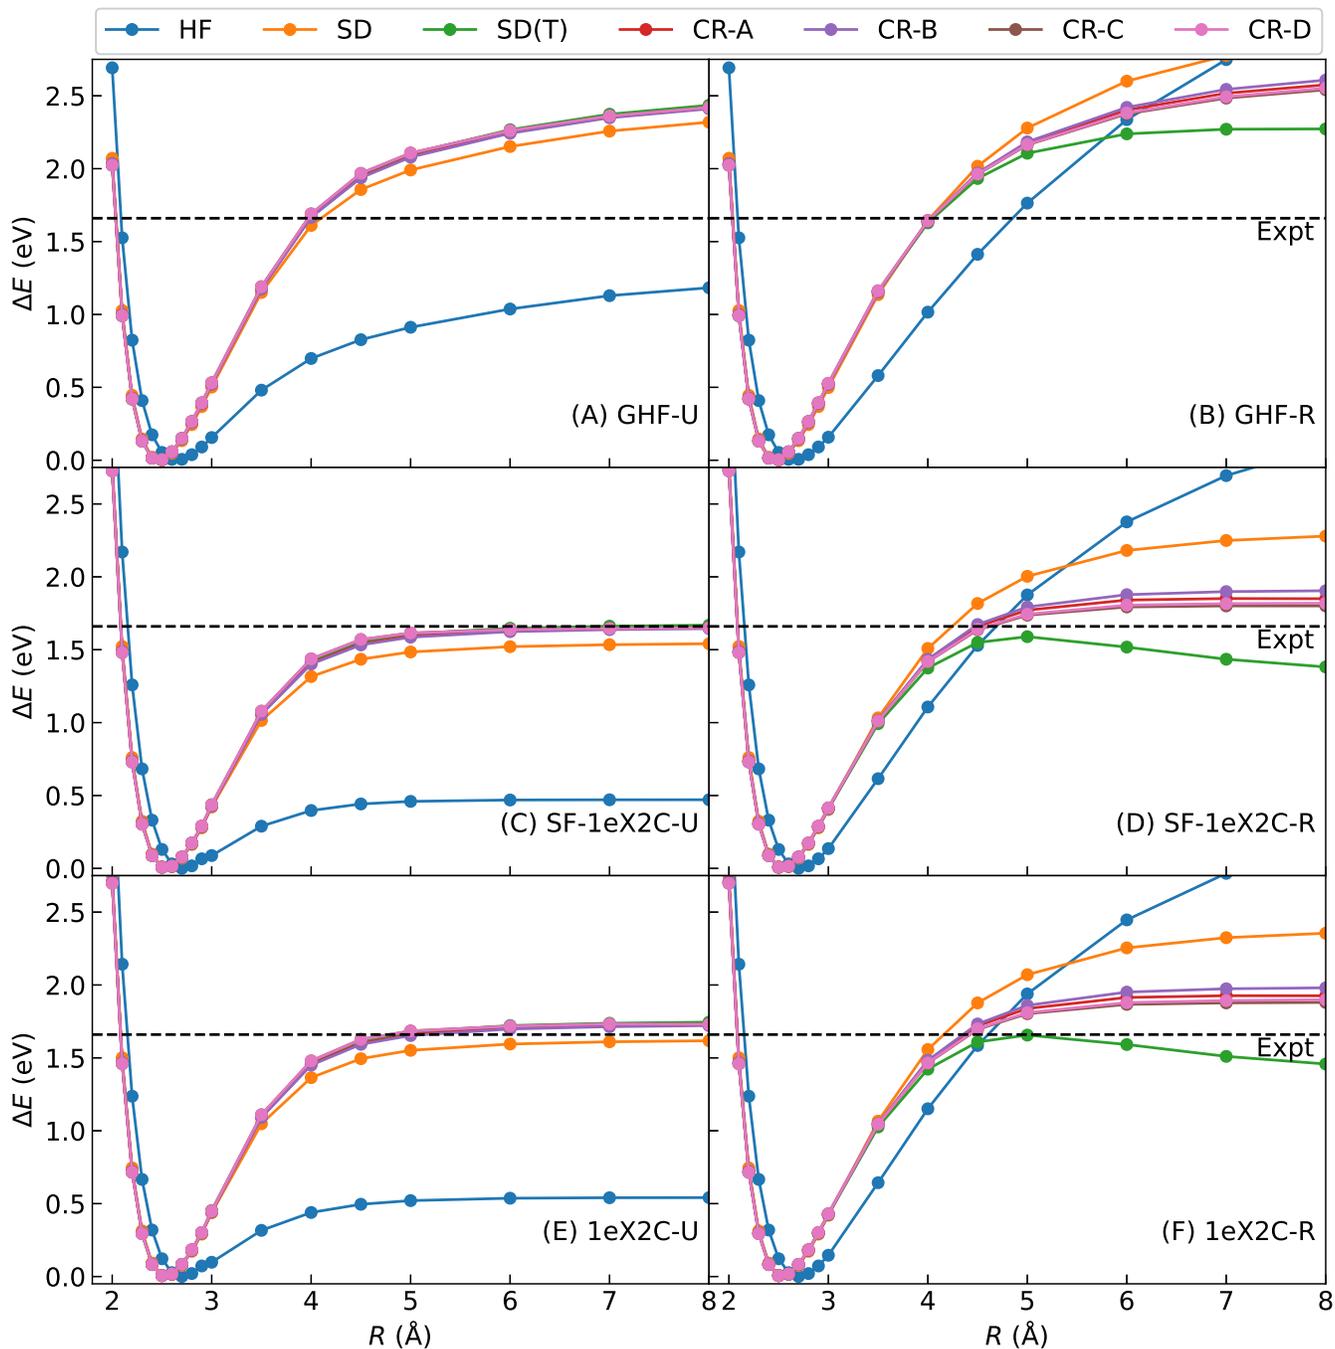

FIG. 2. The PECs of Ag_2 obtained in this work using the ANO-RCC-VDZP basis set. The U and R labels indicate Kramers-unrestricted and restricted reference curves, respectively. Each PEC is shifted relative to the energy at R_e (cf. Table III).

SF-1eX2C- and 1eX2C-CCSD(T) due to the artificial hump around 5 Å.

We now consider the remaining spectroscopic properties tabulated in Table III. For the equilibrium distance, it is noteworthy that the R_e estimate for Ag_2 does not show the expected shortening upon the inclusion of relativistic effects. GHF-based CC predicts a bond length that is too short compared to experiment by about 0.6–0.7 Å. Spin-free relativistic

effects (SF-1eX2C) increase the bond length, resulting in R_e values that are too large by about 0.1 Å. Spin-orbit coupling effects (1eX2C) in turn lead to modest reductions in the equilibrium bond lengths, by roughly 0.002–0.005 Å. In terms of correlation effects, triples corrections have a smaller impact on R_e for Ag_2 than for Cu_2 . Similar patterns can be identified for the ω_e estimates in Table III. The harmonic frequency characterizing the GHF-based PECs are only 10 cm^{-1} lower

TABLE III. Spectroscopic constants for Ag_2 obtained using various CC methodologies with the ANO-RCC-VDZP basis set and different levels of mean-field relativistic treatment.

^a The numbers outside and inside parentheses refer to Kramers-unrestricted and restricted dissociation energies, respectively. The latter estimates are computed as $D_e = E(R = 8.00 \text{ \AA}) - E(R = R_e)$.

^b D_e computed using the D_0 value compiled in Ref. 107 and ω_e of Ref. 116. R_e from Ref. 119.

than the experimentally obtained value, indicating that the PECs are slightly too flat near the equilibrium region, whereas the SF-1eX2C and 1eX2C PECs overshoot the harmonic frequency by about 20 cm⁻¹. In these cases, the triples correction changes the ω_e value by only 1–2 cm⁻¹. The fact that non-relativistic calculations yield superior estimates of the spectroscopic constants, R_e and ω_e , than can be obtained from calculations that include more complete description of the physics suggests a cancellation of errors that is likely due to basis set size effects. This effect is not negligible for Ag_2 , where the ANO-RCC-VDZP basis set has fewer unoccupied (78) than occupied (94) spin orbitals, indicating the need of larger basis sets for post-HF calculations, especially when all electrons are correlated.

C. Au_2

The last system in our investigation is the Au_2 dimer, for which we computed the ground $^1\Sigma_g^+$ state dissociating into two ^{197}Au atoms with ^2S ($[\text{Xe}] 5d^{10}4f^{14}5s^1$) configurations. Gold dimer has attracted a great deal of attention from the quantum chemistry community because the relativistic effects are much more pronounced in Au_2 than in the lighter dimers discussed above. For example, the experimentally determined bond length for Au_2 , 2.4719 Å,^{107,124} is slightly shorter than the corresponding value for Ag_2 despite the increased size of Au atom compared to Ag atom. Au_2 has long served as a benchmark system for relativistic quantum chemistry calculations, and its ground-state PEC has been the subject of thorough experimental and theoretical examinations,^{98,107,110,111,115,124–133} with the experiments providing consistent and reliable estimates of D_e (2.30 eV) and ω_e (190.9 cm⁻¹),^{107,124,125,131} along with the aforementioned R_e value. However, to the best of our knowledge, prior correlated calculations of the gold dimer have all relied on the frozen-core approximation or effective core potentials.^{98,132,133} As such, our calculations, the results of which are provided in Fig. 3 and Table IV, represent the first all-electron correlated relativistic treatment of this system.

The data in Fig. 3 make it quite clear that the non-relativistic results shown in panels (A) and (B) are wrong even at the qual-

itative level, overestimating the experimentally determined dissociation energy by a factor of about 16 (cf. Table IV), even with the inclusion of triples effects from CCSD(T). This observation is notable, given that correlated, non-relativistic estimates of D_e from the literature^{132,133} are in much better agreement with experiment. There are several possible sources of the enormous error we observe, relative to experimental and theoretical estimates for D_e found in the literature. First, Refs. 132 and 133 do not correlate all electrons, whereas we do. Thus, we expect an explicit treatment of at least spin-free relativistic effects to be important here; we cover this case in the next paragraph. Second, we correlate all electrons, but the basis set employed (ANO-RCC-VDZP) was not optimized for all-electron calculations;¹⁴⁷ a brief basis set study in Sec. IV D confirms that the basis set choice is indeed problematic. Before moving on to discuss relativistic treatments of this system, we note that we did not perform GHF-based CR-CC(2,3) calculations because, based on the relative behavior of CCSD(T) and CR-CC(2,3) for Cu_2 and Ag_2 , we do not expect CR-CC(2,3) to offer much of an improvement over CCSD(T) for this case.

As was observed for Ag_2 , spin-free relativistic effects (SF-1eX2C) lead to a dramatic improvement in both the Kramers-unrestricted and restricted PECs as shown in Fig. 3(C) and (D). Indeed, at least using the ANO-RCC-VDZP basis set, the Kramers-unrestricted SF-1eX2C-CCSD PEC dissociation energy is quite close to the experimentally determined value, with the CCSD(T) and CR-CC(2,3) triples correction deepening the potential well by 0.15–0.17 eV or 6%–7% compared to the CCSD result. As shown on panel (D), the Kramers-restricted SF-1eX2C-based PECs are too deep compared to the experimental dissociation energy, producing errors in the order of more than 1 eV, in the case of CCSD, or about 0.4 eV, in the case of the CR-CC(2,3) variants. It is also noteworthy that in the case of Au_2 , the spread between the lowest and highest CR-CC(2,3) dissociation energy estimates, provided by variants C and B, respectively, is 0.13 eV, which is about 30% and 300% higher than the analogous values reported for Ag_2 and Cu_2 , respectively.

Based on the results obtained for the copper and silver dimer, and relying again on the fact that spin-orbit coupling effects should be minimal for the $^1\Sigma_g^+$ state of the gold dimer,

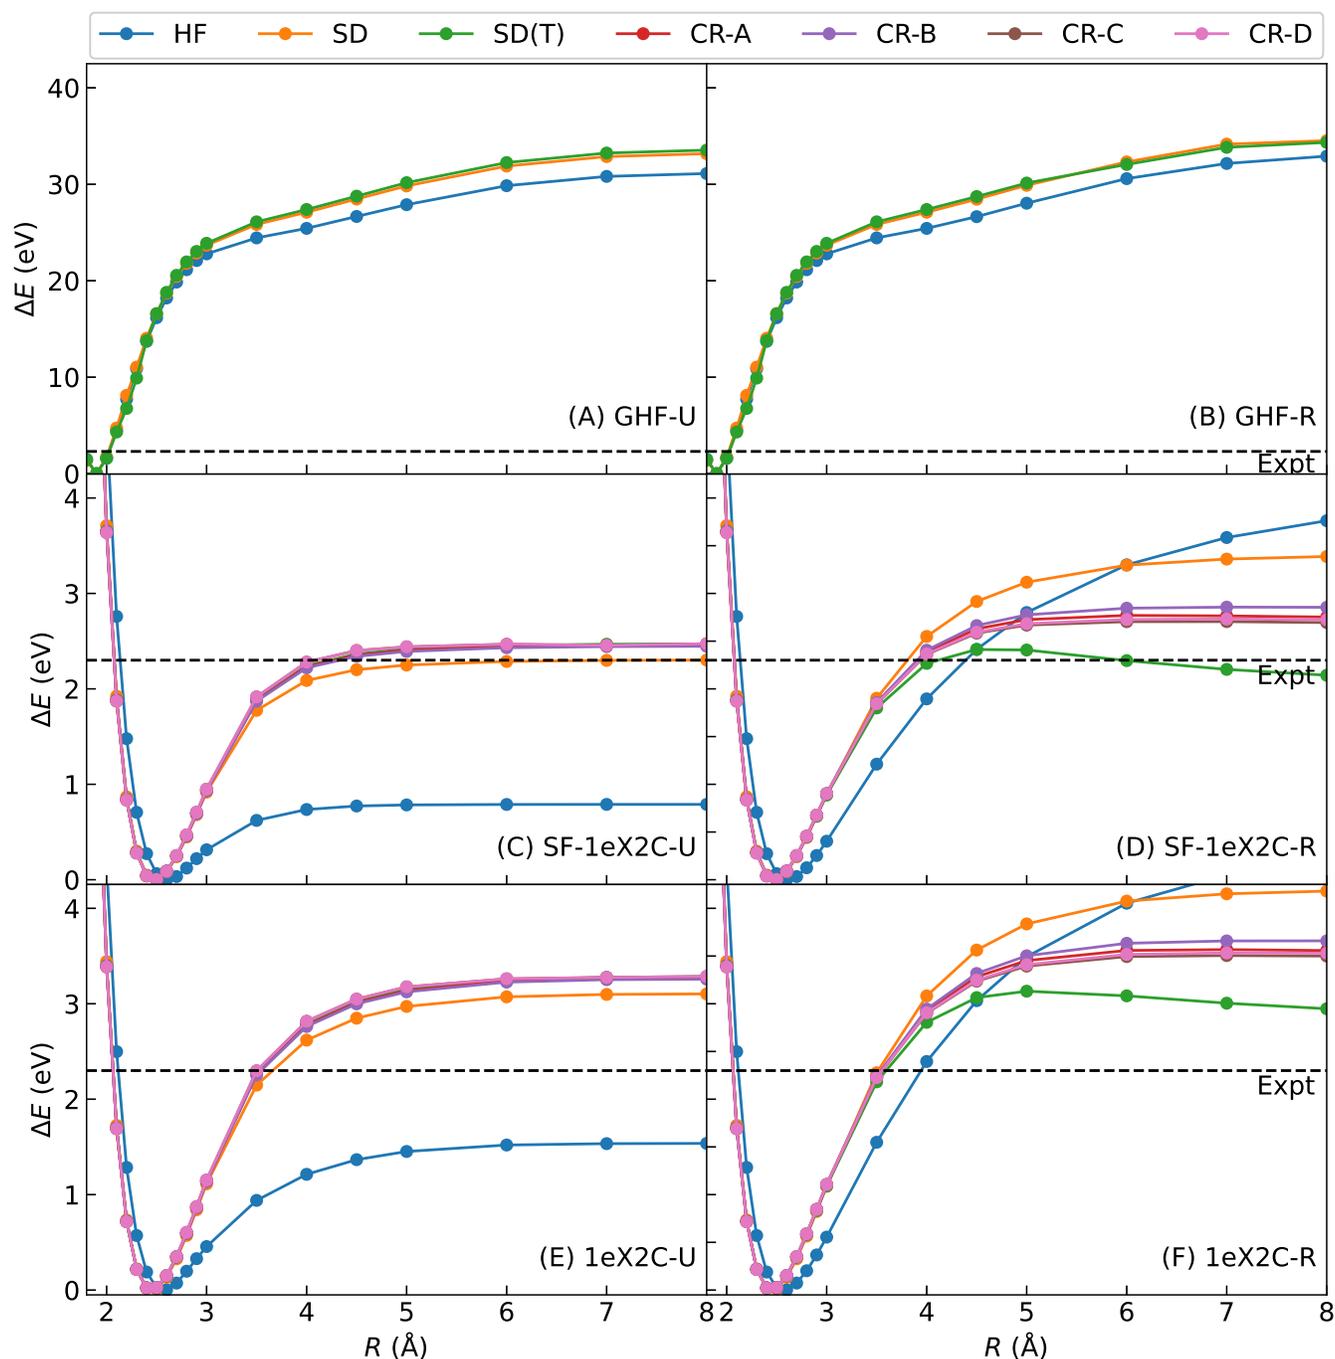

FIG. 3. The PECs of Au_2 obtained in this work using the ANO-RCC-VDZP basis set. The U and R labels indicate Kramers-unrestricted and restricted reference curves, respectively. Each PEC is shifted relative to the energy at R_e (cf. Table IV).

one may have anticipated that the 1eX2C-based results would not differ significantly from the SF-1eX2C-based ones. However, this is clearly not the case for Au_2 , within the ANO-RCC-VDZP basis. Indeed, Fig. 3(E) and (F) show that each of the 1eX2C-based PECs are deeper by about 0.8 eV as compared to their SF-1eX2C counterparts shown in panels (C) and (D), regardless of the unrestricted or restricted nature of the reference curve. This substantial change in the PEC suggests

that a more complete treatment of relativity is more important than high-order electron correlation effects for this system, since the changes in the 1eX2C PECs due to triples corrections on top of CCSD are practically identical to the ones observed in the SF-1eX2C case. More importantly, this large change again points to a potential deficiency in the basis set we have used.

We now analyze the convergence of the different CC meth-

TABLE IV. Spectroscopic constants for Au_2 obtained using various CC methodologies with the ANO-RCC-VDZP basis set and different levels of mean-field relativistic treatment.

^a The numbers outside and inside parentheses refer to Kramers-unrestricted and restricted dissociation energies, respectively. The latter estimates are computed as $D_e = E(R = 8.00 \text{ \AA}) - E(R = R_e)$.

^b Calculations not performed because the reference curve has a significantly wrong shape compared to the expected result.

^c Refs. 107, 124, 125, and 131.

ods, using the difference between Kramers-unrestricted and restricted estimates of D_e as a proxy for convergence toward the exact limit. Regardless of the relativistic treatment used, CCSD produces an error window of about 1.1 eV, which, similar to the Ag_2 case, is almost half of the experimentally derived value of D_e itself. The CR-CC(2,3) triples corrections vastly reduce this uncertainty to only 0.24–0.40 eV. It is encouraging to see that, while the 1eX2C PECs show obvious problems when compared to their SF-1eX2C counterparts, the convergence behavior of CCSD, CCSD(T), and especially CR-CC(2,3) remains similar to that observed for the copper and silver dimers. Given that the correlated 1eX2C-based estimates for D_e lie above 3 eV, this convergence analysis suggests that remaining higher-order correlation effects (from quadruple excitations, for example), will not significantly improve the situation, and, thus, the issue is likely a basis set effect.

Before moving on to discuss the role of the basis set in this system, we analyze the remaining spectroscopic parameters for $\text{Au}_2/\text{ANO-RCC-VDZP}$ that are reported in Table IV. In terms of the equilibrium bond distance, the SF-1eX2C-based CCSD, CCSD(T), and CR-CC(2,3) R_e estimates are all only about 0.01 Å longer than the experimentally derived value of Refs. 107 and 124, whereas their 1eX2C-based counterparts are consistently about 0.02 Å too short. The differences among methods are more apparent in the harmonic frequency estimates, which is an indicator of the quality of the curvature of PEC near the equilibrium geometry. The SF-1eX2C-CCSD, CCSD(T), and CR-CC(2,3) PECs are characterized by ω_e values that are about 2–5 cm⁻¹ lower than the experimentally derived 190.9 cm⁻¹ estimate. In contrast, triples corrections within the 1eX2C framework worsen the estimates of ω_e , giving values that are more than 40 cm⁻¹ too high.

D. Basis set effects

The results of our CC calculations for Cu_2 , Ag_2 , and Au_2 carried out within the ANO-RCC-VDZP basis give rise to an interesting observation. As noted in Ref. 147, the ANO-RCC basis set was not designed for core-electron correlations. Nev-

ertheless, ANO-RCC-VDZP-based results for Cu_2 and Ag_2 are in good agreement with the available experimental data for these systems, even with all electrons correlated and spin-orbit coupling taken into account. The drastic reduction in the quality of the 1eX2C-based $\text{Au}_2/\text{ANO-RCC-VDZP}$ PECs compared to their SF-1eX2C counterparts, though, certainly reveals issues with core correlations, particularly in the presence of spin-orbit coupling, when using this basis set. In this section, we investigate the effects of basis set size and contraction schemes on the convergence of 1eX2C-based HF, CCSD, and CCSD(T) energetics.

Let us begin by considering the basis set contraction (and truncation) scheme used in the calculations discussed in the preceding subsections. The ANO-RCC-VDZP basis set is a subset of the full ANO-RCC basis set, which was optimized using the Douglas–Kroll–Hess Hamiltonian and complete-active-space second-order perturbation theory accounting for valence and semicore electron correlations. The ANO-RCC-VDZP, VTZP, and VQZP basis sets are obtained by simple truncation of the full ANO-RCC basis set to obtain correlation-consistent-style contracted shells without re-optimizing the contraction coefficients. We compare this family of basis sets to the segmented contracted error-consistent basis sets of Refs. 150 and 151, which were optimized using 1eX2C-HF with spin-orbit coupling effects. The x2c-SVPall-2c, x2c-TZVPall-2c, x2c-TZVPPall-2c, and x2c-QZVPPall-2c bases have additional inner *p*- and *d*-type function, compared to their non-2c counterparts, to account for the proper *p*- and *d*-shell splittings.^{150,151} A comparison of the contracted atomic functions for the ANO-RCC and segmented contracted error-consistent basis sets is reported in Table V.

Figure 4 depicts 1eX2C-based PECs for Au_2 computed using the ANO-RCC-VDZP and x2c-SVPall-2c basis sets, the latter of which is the smallest of that family of basis sets. As shown in Fig. 4(A), the SF-1eX2C-HF PECs are insensitive to the choice of basis set. CCSD and CCSD(T) display only slightly larger sensitivity, with the dissociation limits computed using these two basis sets differing by roughly 0.15 eV. However, as the results in panel (B) indicate, 1eX2C-HF, CCSD, and CCSD(T) energies computed in different basis sets differ dramatically once we include spin-orbit coupling

TABLE V. The list of atomic basis function shells for Cu, Ag, and Au employed in this work.

effects. For the correlated calculations, we see substantial improvements in the description of the Au₂ PEC with the x2c-SVPall-2c basis. The 1eX2C-CCSD and CCSD(T) D_e and ω_e estimates are now much closer to their experimentally derived values (see Table VI). Interestingly, we do not see similar improvements in equilibrium bond lengths estimated from x2c-SVPall-2c calculations; in both SF-1eX2C- and 1eX2C-based calculations, the R_e values obtained using the x2c-SVPall-2c basis set are all about 0.07 Å longer than the experimental estimate, whereas ANO-RCC-VDZP produces values that are within 0.01–0.02 Å relative to experimental data. Nevertheless, the improvements in D_e and ω_e estimates indicate that the x2c-SVPall-2c basis set is a promising alternative to ANO-RCC-VDZP.

^b Refs. 107, 124, 125, and 131

Table VII summarizes the results of more comprehensive calculations that considered D_e values for Cu₂, Ag₂, and Au₂ determined using 1eX2C-HF, CCSD, and CCSD(T), within the ANO-RCC-VDZP, VTZP, VQZP, and full ANO-RCC basis sets, as well as the x2c-SVPall-2c, x2c-TZPall-2c, x2c-TZVPPall-2c, and x2c-QZVPPall-2c bases. In the case of Au₂, we also provide additional data for the ANO-RCC basis, augmented by an additional *i*-type function on each Au atom, which is prompted by a statement in Ref. 98 claiming that the interaction in Au₂ can only be described properly by including at the very least *h*-type functions. For the purposes of this analysis, the D_e estimates are computed as the energy difference between two atoms and the lowest-energy point for each dimer, at the CCSD/ANO-RCC-VDZP level of theory,

on the grid defined in Table I, which are $R = 2.20$ Å for Cu₂ and $R = 2.50$ Å for the Ag and Au dimers.

As shown in Table VII, the 1eX2C-HF/ANO-RCC-VDZP dissociation energies are practically converged for Cu₂ and Ag₂, increasing by at most 0.06 and 0.04 eV, respectively, as the basis set quality is increased from the quadruple- ζ -quality truncation to the full set. Interestingly, in both of these dimers, the 1eX2C-HF dissociation energy increases from double- to quadruple- ζ but then decreases once the full ANO-RCC basis set is reached, becoming more similar to the ANO-RCC-VDZP or VTZP estimates. The behavior is more unpredictable for Au₂, where the 1eX2C-HF dissociation energy estimate shows no clear convergence pattern. With the full ANO-RCC basis set, the D_e estimate is 0.85 eV, which is slightly more than half of the value obtained using ANO-RCC-VDZP. The addition of an *i*-type primitive to each of the Au atom does not significantly change the HF energy, indicating that the full ANO-RCC basis set can be considered converged in terms of 1eX2C-HF energetics for the gold dimer (as well as the lighter analogs).

The D_e estimates from correlated approaches show much worse convergence properties. Going from triple- to quadruple- ζ -quality basis, the D_e is clearly not converged, and massive reductions are observed once the full set is used, again, bringing the estimates more in line with those from double- or triple- ζ -level calculations. For Cu₂, D_e obtained using CCSD increase monotonically from 1.89 eV (ANO-RCC-VDZP) to 2.20 eV (ANO-RCC-VQZP) case, but a much lower value (1.77 eV) is obtained with the full ANO-RCC set. The CCSD(T) energetics behave similarly, but the correlation effects due to connected triple excitations, quantified here as the difference between CCSD(T) and CCSD energetics, more than double when going from ANO-RCC-VDZP (0.12 eV) to the full ANO-RCC (0.28 eV). It is also worth mentioning that 1e-X2C-CCSD(T)/ANO-RCC predicts a D_e value in excellent agreement with experiment. The CCSD(T)/ANO-RCC-VDZP estimate is also quite good but results from a fortuitous cancellation of error, given that the basis is far from complete. The situation is similar for the silver dimer, in which the CCSD and CCSD(T) D_e estimates increase as the basis set size also increases from ANO-RCC-VDZP to VQZP, and finally dropping at the use of the full ANO-RCC basis. The effects of triples correlations on the dissociation energy of Ag₂ are also of the similar order of magnitude to those observed in Cu₂, ranging from 0.13 eV in the ANO-RCC-VDZP case to 0.21 eV in the full ANO-RCC set. Unlike in the case of Cu₂, unconverged 1eX2C-CCSD and CCSD(T) estimates obtained using the ANO-RCC-VDZP basis are not in good agreement with the experimentally derived value.

The basis set convergence issues for correlated approaches persist in the gold dimer, where increasing the basis from ANO-RCC-VDZP to ANO-RCC-VTZP makes the D_e value worse, as compared to experiment, by 0.64 eV, and the ANO-RCC-VQZP basis set produces a result that is intermediate in quality between the ANO-RCC-VDZP and VTZP values. Only the full ANO-RCC set results in a reasonable dissociation energy value from CCSD (2.16 eV), which is an 0.93 eV or 30% decrease from the estimate obtained using ANO-

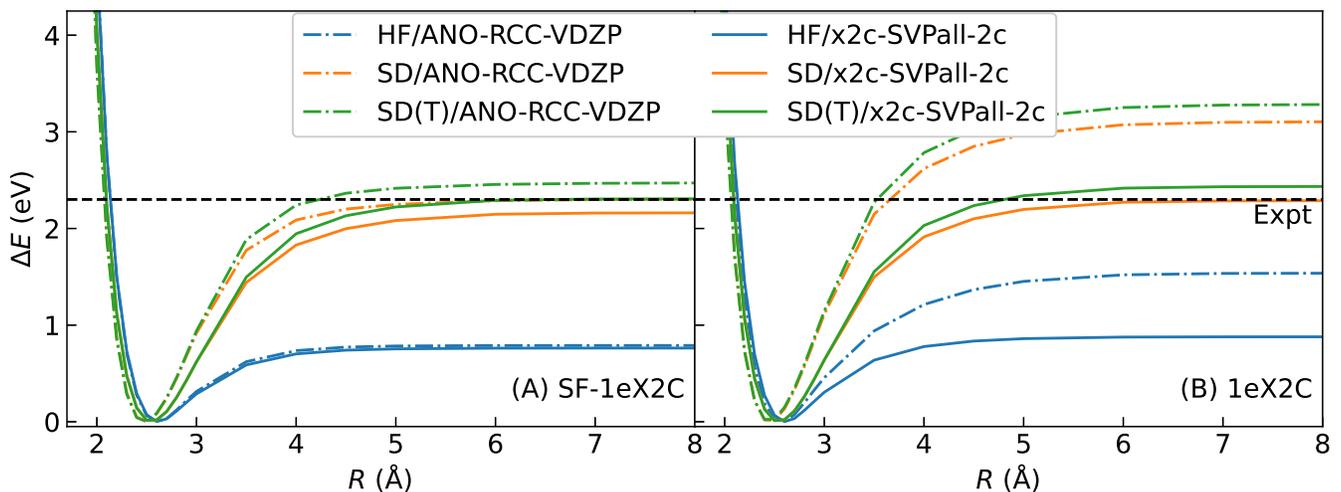

FIG. 4. The Kramers-unrestricted HF, CCSD, and CCSD(T) PECs of Au_2 obtained in this work using the ANO-RCC-VDZP and x2c-SVPall-2c basis sets.

RCC-VDZP. The addition of i -type functions does not significantly affect the correlated estimates of D_e , changing the CCSD value by merely 0.01 eV. The convergence of D_e with respect to the addition of an i -type primitive is consistent with the claim in Ref. 98 that one should to include at least h -type functions in the calculation; apparently higher angular momentum functions are not required, at least for obtaining good estimates of D_e . This consistency comes with the caveat that the present calculations correlate all electrons, whereas those in Ref. 98 correlated only valence and semicore correlation, in combination with with effective core potentials. Although we did not complete the CCSD(T)/ANO-RCC and CCSD(T)/ANO-RCC+ i calculations for Au_2 , as indicated by the missing numbers in Table VII, the triples energy corrections for the ANO-RCC-VDZP–ANO-RCC-VQZP cases, of 0.17–0.25 eV, are still similar in magnitude to their copper and silver dimer counterpart. Thus, we can anticipate these CCSD(T) D_e estimates to be at most 0.2 eV higher than the experimental result.

We now turn our attention to the convergence of the D_e estimates computed within the segmented contracted error-consistent basis sets of Refs. 150 and 151 (see Table VII). First, the D_e values from 1eX2C-HF carried out within these basis sets converge rapidly for Cu_2 and Ag_2 . For Au_2 , we observe slightly larger variations in D_e as we increase the ζ -level (up to 0.06 eV), but these fluctuations are minuscule compared to those observed for Au_2 with truncated ANO-RCC basis sets. Moreover, the quality of the 1eX2C-HF D_e from the smallest segmented contracted error-consistent basis set (x2c-SVPall-2c) is comparable to that of the D_e from 1eX2C-HF in the full ANO-RCC set. Second, the situation is similar for correlated calculations. The D_e values converge reasonably well; for each dimer, D_e estimates do not change by more than about 0.2 eV when we go from the smallest to largest ζ levels. Third, aside from the difference in convergence properties, we do find some consistent behavior between basis set families. For example, the triples contributions

to D_e computed using CCSD(T) are comparable regardless of the basis (on the order of 0.15–0.25 eV). Lastly, the 1eX2C-CCSD(T)/x2c-QZVPPall-2c results for the Cu_2 and Ag_2 are in excellent agreement with experiment. For Au_2 , given that (i) the CCSD(T) triples correction in the x2c-TZPPall-2C basis set is ~ 0.2 eV and (ii) the D_e value computed using CCSD appears to be converged using the quadruple- ζ basis, we can expect that 1eX2C-CCSD(T)/x2c-QZVPPall-2c result should be within 0.1 eV from the experimental estimate of 2.30 eV.

V. CONCLUSIONS

We have implemented all-electron relativistic (1eX2C) non-iterative triples corrections to CCSD, namely, CCSD(T) and CR-CC(2,3), in the Chronus Quantum software package. These codes have been applied to evaluate estimates of spectroscopic constants in the coinage metal dimers, Cu_2 , Ag_2 , and Au_2 . Using suitable basis sets, D_e estimates are in excellent agreement with experiment, with triples correlation effects contributing 0.1–0.2 eV. While ANO-RCC sets were not optimized for all-electron calculations, our calculations on Cu_2 and Ag_2 dimers nonetheless give reasonable results as compared to experiment. On the other hand, calculations on Au_2 reveal that truncated ANO-RCC basis sets do not provide a reliable description of spin-orbit coupling effects in this system. Other basis set families optimized for all-electron calculations with spin orbit coupling (*i.e.*, the segmented contracted error-consistent basis sets of Refs. 150 and 151), appear to give more consistent and reasonable results at varying ζ -levels, at least for the systems studied in this work.
