

Effect of biquadratic magnetic exchange interaction in the 2D antiferromagnets MPS_3 ($M = \text{Mn, Fe, Co, Ni}$)

M. Amirabbasi and P. Kratzer

Fakultät für Physik and CENIDE, Universität Duisburg-Essen, Lotharstraße 1, 47057 Duisburg, Germany

The two-dimensional van der Waals (vdW) materials MPS_3 ($M = \text{Mn, Fe, Co, Ni}$) display antiferromagnetic ordering of the magnetic moments at the transition metal ions. The possibility to exfoliate thin layers that preserve the magnetic order makes these materials interesting for numerous applications in devices that require integration of flexible patches of magnetic materials, e.g. in antiferromagnetic spintronics. Hence, an improved understanding of their magnetic properties is desirable. Here, we parameterize spin Hamiltonians for a monolayer of all four materials of this class using density functional theory plus Hubbard U calculations. We provide a step-by-step guide for calculating the magnetic exchange interactions and magnetic anisotropy energy using the (non-)collinear DFT+ U (+ SOC) approach with a suitably chosen U for each material. It is found that the biquadratic interactions gain in importance while moving through the 3d series. Retaining the leading terms of a Holstein-Primakoff-transformed spin Hamiltonian, the magnon spectra are calculated. While MnPS_3 is found to be an almost isotropic antiferromagnet with a tiny gap, the biquadratic interaction opens an increasingly wider gap for FePS_3 , CoPS_3 and NiPS_3 . In line with this observation, Monte Carlo simulations demonstrate that the biquadratic interactions contribute to a systematic rise in the Néel temperature from FePS_3 to NiPS_3 .

I. INTRODUCTION

Transition metal phosphorus trisulfides, denoted as MPS_3 where M can be Mn, Ni, Fe, or Co, represent a class of materials that have gained significant attention^{1–3} for their remarkable electronic, magnetic, and optical characteristics. These materials are particularly noted for their impressive optoelectronic properties⁴, including strong absorption in the visible to near-infrared spectrum and efficient charge separation and transport⁵. They feature a layered structure similar to graphene, which not only piques interest for fundamental research but also facilitates their exfoliation into two-dimensional layers. These thin layers often exhibit properties distinct from their bulk counterparts, offering a rich avenue for investigating new physical phenomena and potential technological applications.

Magnetism is a subtopic in the field of 2D materials that has drawn significant interest recently⁶. The magnetic nature of MPS_3 is a key aspect that this article aims to explore in depth. By calculating the spin Hamiltonian and analyzing the magnon spectrum, we seek to unravel the magnetic properties of these materials. The study of the magnon spectrum in MPS_3 is not just a topic of fundamental interest; it also has significant implications for the fields of spintronics⁷ and magnonics⁸, where electron spins and magnons are utilized for advanced information processing and storage. The magnon spectrum plays a vital role in determining the magnetic behavior of a material, such as its magnetic ordering temperature and characteristics crucial for spintronic applications. The spin Hamiltonian, which includes both isotropic and anisotropic exchange interactions, provides insights into the interactions between magnetic moments and their tendencies to align in specific directions. The unique layered structure and magnetic properties of MPS_3 materials offer a template for

designing new materials with tailored properties. By understanding the interplay between structure, magnetism, and electronic properties in these materials, researchers can engineer new compounds with desired functionalities for specific applications.

In the realm of 2D monolayer systems governed by a Heisenberg Hamiltonian, which inherently encompasses short-range magnetic interactions and preserves spin rotational symmetry, a theorem proposed by Mermin and Wagner⁹ precludes the establishment of long-range ferromagnetic (FM) or antiferromagnetic (AFM) ordering at any finite temperature. This theorem's foundation rests on the inherent characteristics of the isotropic Heisenberg Hamiltonian, notably its continuous symmetry, which facilitates the existence of long-wavelength spin waves without an energy gap. These spin waves, owing to their gapless nature, are thermally excitable at any finite temperature, posing a significant challenge to the sustenance of long-range magnetic order in low-dimensional structures. In contrast, scenarios that involve a breach in the spin rotational invariance, exemplified by anisotropic magnetic interactions within the framework of a two-dimensional Ising model, alter this paradigm. In such cases, the introduction of anisotropy leads to the formation of an energy gap in the spin wave spectrum. This gapped spin wave spectrum plays a crucial role in stabilizing long-range magnetic order by diminishing the influence of thermal fluctuations. Such stabilization becomes prominent below a specific transition temperature, marking a stark divergence from the behavior predicted by the isotropic Heisenberg model in two-dimensional systems. A principal objective of the research outlined in this document is to examine the presence and implications of anisotropic exchange interactions within MPS_3 materials, with specific focus on phenomena such as single-ion anisotropy (SIA) and Dzyaloshinskii-Moriya interactions (DMI)¹⁰. This investigation is crucial in resolving the key

question of whether two-dimensional (2D) MPS_3 materials can retain their magnetic order during the transition from bulk to monolayer structures. Additionally, in this study, we are examining the impact of biquadratic interactions in MPS_3 materials. Since these materials have a collinear magnetic order, we expect that the biquadratic interaction parameter might have a negative value. This prediction aligns with the theoretical framework outlined in Eq. (1) of the paper. Understanding these biquadratic interactions is crucial for gaining a deeper understanding of the complex magnetic properties of these materials, particularly as they are reduced to lower-dimensional states.

In terms of its structural properties, MPS_3 crystallizes in a monoclinic structure characterized by the $C2/m$ space group. The material's bulk structure is made up of layers stacked together and held in place by van der Waals forces. Within each layer, a transition metal ion M is surrounded by six sulfur atoms, forming a distorted octahedral structure that contributes to the formation of a hexagonal lattice interconnected by S ions. Central to these hexagonal arrangements are two phosphorus ions, each bonded to three sulfur ions. The magnetic moments in MPS_3 , originating from the unpaired d-electrons of the M ions, interact with each other, leading to the emergence of magnetic order. This aspect of magnetic interaction and order is a cornerstone of the intriguing properties exhibited by MPS_3 materials, underlining their potential for a wide array of applications in the field of materials science. The paper is structured as follows: In Section II we provide details of the electronic structure calculations and Monte Carlo (MC) simulations. In Section III we first report on the structural optimization and magnetic order. We then describe the electronic structure before detailing the magnetic interactions. Finally, in Section V we discuss the implications of our results for MPS_3 single-layers and in the broader context of magnetic vdW layered materials.

II. METHODS

The present study employs Density Functional Theory (DFT) to investigate the magnetic and structural properties of materials. DFT is a well-established computational approach for the evaluation of electronic properties of materials. However, it may not accurately capture the electronic structure of materials with strongly correlated electrons, such as transition metal oxides or rare earth magnets, using standard DFT. To address this issue, the DFT+ U method is commonly utilized, which incorporates an on-site Coulomb interaction term (U) to better account for the electronic interactions within the material. To apply the DFT+ U method to investigate magnetic properties, the appropriate value of the U parameter must first be determined. This value can be derived experimentally or from previous theoretical studies. It is crucial to choose the correct U value, as it directly af-

fects the computed magnetic properties of the material. In this work, the DFT calculations were performed using the Quantum Espresso¹¹ (QE) and the all-electron FLEUR^{12,13} code. The wavefunctions and charge density were expanded in plane waves using a cutoff of 50 Ry and 550 Ry, respectively, in the QE calculations. The present study utilized the FLEUR-based calculations to investigate the noncollinear(+SOC) magnetic properties of MPS_3 . The wave function expansion cutoff in the interstitial region is set to $k_{\max} = 3.8 \text{ a.u.}^{-1}$.

Table I: Lattice constants of optimized geometry in GGA+ U . The optimum U values have been chosen through comparing the calculated bandgap with its experimental values.

Material	U_{eff} (eV)	a (Å)	b (Å)	E_g (eV)
FePS ₃	2.22	6.017	6.052	1.23
FePS ₃	exp.	5.940	5.972	1.23 ¹⁶ , 1.44 ¹⁷
MnPS ₃	3.0	6.193	6.193	2.0
MnPS ₃	exp.	6.076	6.076	2.94 ^{1,18}
CoPS ₃	3.0	5.954	5.954	1.35
CoPS ₃	exp.	5.901	5.901	1.5 ¹⁹
NiPS ₃	5.7	5.828	5.829	1.89
NiPS ₃	exp.	5.812	5.813	1.6 ¹

Semicore states, specifically the 3s and 3p orbitals of the transition metal, are included in the calculations. In the selection of Muffin-tin radii for magnetic ions across various systems, considerations are made regarding the influence of semicore electrons and lattice constants. As delineated in Tab. I, the lattice constants exhibit a decremental trend from Mn to Ni. In alignment with this observation, the Muffin-tin radii for Mn, Fe, Co, and Ni have been determined as 2.9, 2.8, 2.7, and 2.6 atomic a.u., respectively. To enhance the precision in the comparative analysis of calculations, the Muffin-tin radii for P and S have been consistently set at 1.90 a.u. and 1.49 a.u., respectively, across all studied materials. The spin magnetic moments from DFT+ U calculations by choosing these values are found to be in reasonable agreement with the values predicted by Hund's rule. The exchange-correlation energy is approximated using the generalized gradient approximation (GGA) in the Perdew-Burke-Ernzerhof parameterization PBE¹⁴. To account for the strong electron-electron interactions in materials with correlated electrons, the DFT+ U approach is utilized. For a better description of the low-temperature ground state of MPS_3 , we employ the GGA+ U approach, following Dudarev's approach¹⁵, which includes a spherically symmetric effective on-site Coulomb repulsion U_{eff} to correct for the on-site electron-electron interaction (U) of the 3d orbitals of the Fe atoms.

To determine the type of magnetic order of the ground

Figure 1: (a) $2 \times 2 \times 1$ supercell of a MPS_3 monolayer. The purple, blue, and yellow spheres are transition metals, P and S ions, respectively. The dashed line shows the primitive cell containing two M ions. (b) Schematics of exchange interactions for different neighbors.

Figure 2: Different antiferromagnetic ground states: (a) Néel ground state of $MnPS_3$ (b) Long-bond zigzag found in $FePS_3$ (the vertical Fe – Fe spacing in the figure is the 'long' one), and (c) Short-bond zigzag found in $CoPS_3$ and $NiPS_3$. It should be noted that according to our GGA+ U +SOC calculations, the spins prefer to align along the b -axis for Mn, Ni, and Co, but along the c -axis for $FePS_3$.

state, we define a model spin Hamiltonian :

$$H_{\text{spin}} = H_{\text{Heis}} + \frac{1}{2}B \sum_{\text{n.n}} (\vec{S}_i \cdot \vec{S}_j)^2 + \frac{1}{2}D \sum_{\text{n.n}} \hat{D}_{ij} \cdot (\vec{S}_i \times \vec{S}_j) + \Delta \sum_i (\vec{S}_i \cdot \vec{d}_i)^2 \quad (1)$$

where \vec{S}_i represents the direction of magnetic spins, H_{Heis} is the usual Heisenberg Hamiltonian, B , D and Δ are the strengths of bi-quadratic, DMI and SIA, respectively. Moreover, unit vectors \hat{D}_{ij} and \vec{d}_i show the direction of the DMI and the easy axis of magnetization at each site i , respectively. It should be noted that the direction of DMI is determined by Moriya rules¹⁰. Due to the centrosymmetric $2/m$ point group symmetry, the MPS_3 monolayer has a mirror plane perpendicular to the b -axis. According to the Moriya rules, when a mirror plane includes two ions, the D vector should be perpendicular to the mirror plane. Magnetic interactions were obtained by fitting a model Hamiltonian to total energy calculations for various magnetic configurations, as described in ap-

pendix A. The Heisenberg Hamiltonian is given by

$$H_{\text{Heis}} = -\frac{1}{2} \sum_{i \neq j} J_{ij} (\vec{S}_i \cdot \vec{S}_j) \quad (2)$$

Motivated by our previous work on orbital ordering in $FePS_3$, we distinguish between 'close' first neighbors with exchange parameter J_{1a} and 'long-bond' first neighbors with J_{1b} if the distances between the M atoms differ by more than 0.05\AA . In addition, we include interactions up to the forth-nearest neighbors to ascertain the convergence of the expansion. Consequently, the calculations for determining the J parameters require a $2 \times 2 \times 1$ cell (with 40 atoms), and we use a $10 \times 10 \times 1$ Monkhorst-Pack k -point mesh²⁰. The other exchange parameters B , D and Δ were obtained from a primitive cell (with 10 atoms), and we used a $20 \times 20 \times 1$ optimized Monkhorst-Pack k -mesh.

We conduct Monte Carlo simulations, treating the spin as a classical vector of unit length, using the replica exchange method on a $30 \times 30 \times 1$ simulation cell containing 3600 spins. Each spin is subjected to 2×10 steps at each temperature. To minimize the correlation between successive data, we collect statistics every 10 MC steps. The

crystal structure figures are generated using VESTA software²¹.

Magnon spectra are calculated analytically by re-writing the spin operators by bosonic operators using the Holstein-Primakoff transformation²². More details are given in appendix B.

III. RESULTS AND DISCUSSION

In this section, we present the results of our study and provide a comprehensive discussion of their implications for the field.

A. Electronic structure

In our study, we observe the progressive filling of the d-shell across MnPS_3 , FePS_3 , CoPS_3 , and NiPS_3 . In the context of our study, the spin and orbital magnetic moments (Tab. II) are pivotal in understanding their magnetic properties. For MnPS_3 , the Mn^{2+} ion with a $3d^5$ configuration exhibits a high spin state, in line with Hund's rule, leading to a spin moment of $5 \mu_B$ and a negligible orbital moment. Moving to FePS_3 , the Fe^{2+} ions with a $3d^6$ configuration show a spin moment of $4 \mu_B$, consistent with Hund's rule, and the largest orbital moment. In CoPS_3 , Co^{2+} ions feature a $3d^7$ configuration, resulting in a $3 \mu_B$ spin moment. Finally, NiPS_3 , with Ni^{2+} ions having a $3d^8$ configuration, shows a reduced spin moment of $2 \mu_B$. These theoretical predictions, based on the oxidation state and electron configurations, provide a framework for understanding the magnetic behavior of these compounds, although experimental validation is crucial for a comprehensive understanding.

Table II: Spin and Orbital moments of MPS_3 2D magnets.

Material	Spin moment (μ_B)	Orbital moment (μ_B)
$\text{MnPS}_3(3d^5)$	4.68	0.02
$\text{FePS}_3(3d^6)$	3.61	0.77
$\text{CoPS}_3(3d^7)$	2.51	0.22
$\text{NiPS}_3(3d^8)$	1.52	0.11

In this paper, we observe distinct structural and magnetic properties across MnPS_3 , FePS_3 , CoPS_3 , and NiPS_3 . These materials adhere to an ideal honeycomb lattice structure, whereas FePS_3 exhibits a notable deviation with its distorted honeycomb lattice. This unique distortion²³ in FePS_3 at low temperatures leads to a significant difference between the long-bond and short-bond in its zigzag ground state.²⁴ Remarkably, MnPS_3 exhibits a Néel AFM ground state, contrasting with NiPS_3 and CoPS_3 , which both display a zigzag AFM ground state. For FePS_3 , the magnetic order at low temperatures is characterized as a long-bond zigzag, highlighting the impact of lattice distortion on its magnetic properties. These findings elucidate the complex relationship

between lattice structure and magnetic behavior in transition metal phosphosulfides. The different magnetic orders are shown in Fig. 2.

Therefore, high-accuracy geometry optimization is crucial, requiring careful selection of the U parameter and accurate representation of the magnetic order. For MnPS_3 , a primitive cell with two Mn ions is utilized, aligning with its Néel ground state. In contrast, for FePS_3 , CoPS_3 , and NiPS_3 , we employ both $2 \times 1 \times 1$ and $1 \times 2 \times 1$ supercells comprising four magnetic ions to adequately represent short-bond and long-bond zigzag states, respectively. The optimized lattice constants, presented in Tab. I, show excellent correlation with experimental values. The U parameter is meticulously chosen to enhance electron-electron correlation within the d-shells. Determining the optimal U value proves challenging, as the value derived using the Density Functional perturbation theory²⁵ fails to reproduce the experimental bandgap. Consequently, we adjusted the U parameter to align with the experimental bandgap. This adjustment also considers the variability in reported experimental bandgaps for bulk materials, adding to the complexity of accurately determining the U value. The final U parameters, which effectively describe the bandgap, structural properties, and magnetic moments of the ions, are detailed in Table I.

Fig. 3 in our study elucidates the contributions of p and d orbitals from P, S, and M (Mn, Fe, Co, Ni) ions in MPS_3 materials. For FePS_3 , in the energy range extending from the Fermi level to -2 eV, the d orbitals of Fe are predominantly influential, especially for the shallow states. In contrast, deeper energy bands demonstrate a pronounced hybridization between Fe's d-electrons and the p-electrons of sulfur. For MnPS_3 , CoPS_3 , and NiPS_3 , the p orbitals of sulfur exhibit a more pronounced effect below the Fermi energy. This distinct behavior in FePS_3 can be attributed to the crystal field effects arising from its distorted honeycomb lattice, leading to orbital ordering where the in-plane $d_{x^2-y^2}$ orbital plays a pivotal role. This analysis underscores the significant impact of crystal field and lattice structure on the electronic states of these materials.

Fig. 4 depicts the orbital-resolved electronic density of states for MnPS_3 , FePS_3 , CoPS_3 , and NiPS_3 monolayers, provides key insights into how the crystal field affects d-shell splitting. For MnPS_3 , CoPS_3 , and NiPS_3 , the d_{zy} and d_{zx} orbitals are particularly influential near the Fermi energy, a characteristic tied to t_{2g} orbitals. In contrast, for FePS_3 with its distorted lattice, the $d_{x^2-y^2}$ (e_g) orbital becomes more significant. This difference underscores the impact of lattice geometry on electronic properties, particularly in how it influences the behavior of d-sublevels in these materials. Since the magnetic properties in MPS_3 are governed by the super-exchange mechanism, the p-orbital of S ions as intermediate between magnetic ions plays a crucial role. According to Anderson's rule²⁶, when t term as kinetic energy in Hubbard Hamiltonian increases, the J value will get stronger.

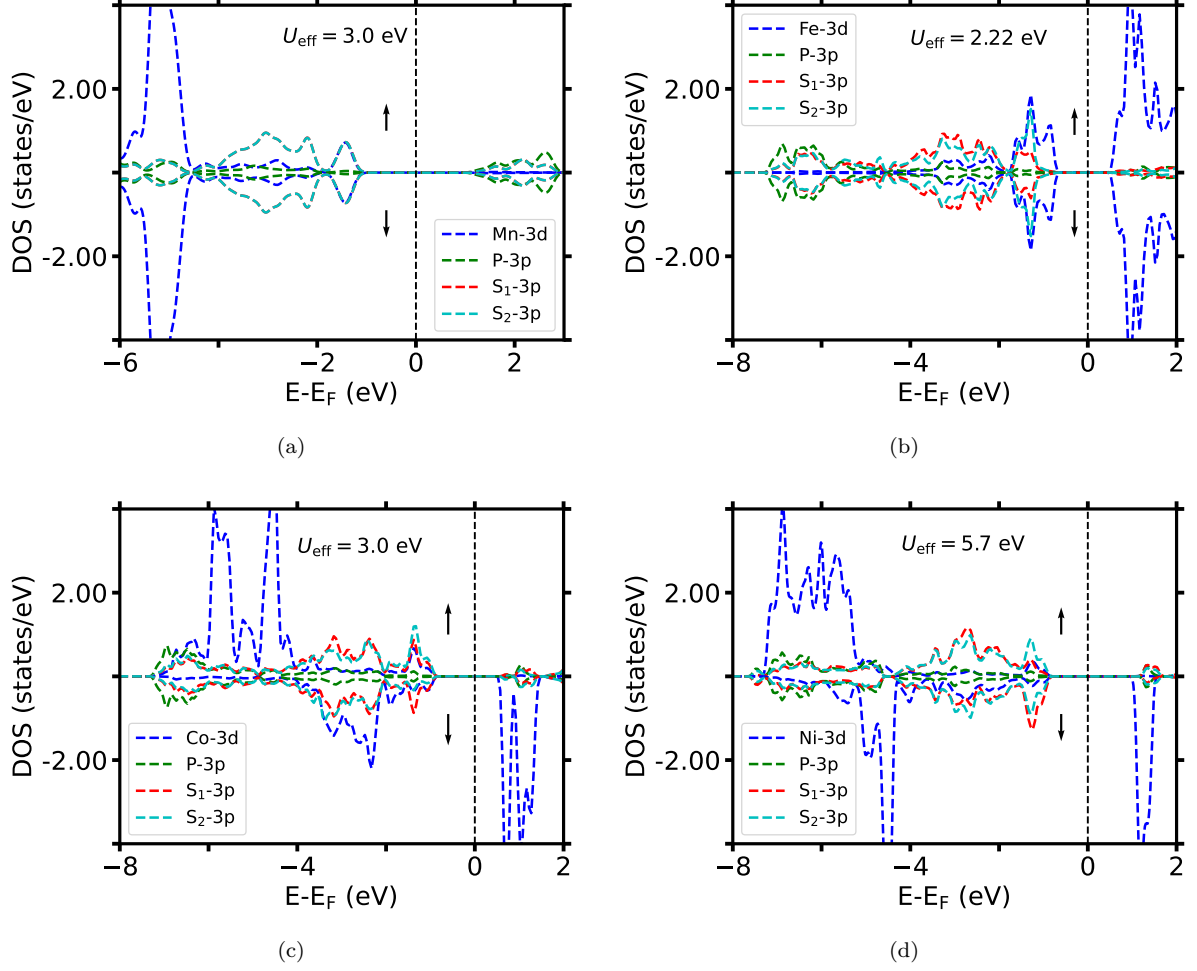

Figure 3: Electronic density of states (DOS) calculated with GGA+ U at optimized lattice coordinates for various magnetic orderings: (a) Néel-AFM (b) Long-bond zigzag (c) Short-bond zigzag. For these calculations, we consider one atom of each species and plot the DOS for spin-up (up arrow) and spin-down (down arrow). The spin-up direction is defined by the majority spin of the magnetic ion selected for the plot. According to Wyckoff's positions, two types of S atoms have different distances from magnetic ions. For Mn, the distances Mn-S₁ and Mn-S₂ are 2.690 and 2.687 Å, respectively. That's why the DOS for S-3p coincide with each other. For Fe, Fe-S₁ and Fe-S₂ are 2.616 and 2.609 Å, respectively. For Co, Co-S₁ and Co-S₂ are 2.523 and 2.520 Å, respectively. For Ni, Ni-S₁ and Ni-S₂ are 3.323 and 3.229 Å, respectively.

Table III: Calculated Heisenberg couplings J_i (meV) up to the forth neighbors, bi-quadratic exchange interaction B (meV), Dzyaloshinskii-Moriya exchange interaction D (meV) and single ion anisotropy Δ (meV) for different U_{eff} (eV) parameters. Negative and positive value denotes AFM and FM exchange interaction, respectively. Note that $|S| = 1$ has been used in the definition of the spin Hamiltonian. By using the obtained couplings, we perform MC simulations to find the Néel (T_N) temperature (K). The temperature value in parenthesis would result if the biquadratic couplings were neglected.

Material	U_{eff}	J_{1a}	J_{1b}	J_2	J_3	J_4	Δ	D	B	T_N
MnPS ₃	3.00	-7.89	-7.89	-0.21	-3.47	0.02	-0.025	0.00	-0.95	76.2 (73.0)
FePS ₃	2.22	-3.26	4.01	-1.24	-5.71	1.50	-0.89	-0.34	-2.10	70.0 (66.9)
CoPS ₃	3.00	3.47	3.47	0.64	-10.85	0.06	-0.14	0.00	-5.53	86.5 (67.7)
NiPS ₃	5.70	2.46	2.46	0.14	-11.58	0.06	-0.22	0.00	-6.91	94.0 (70.6)

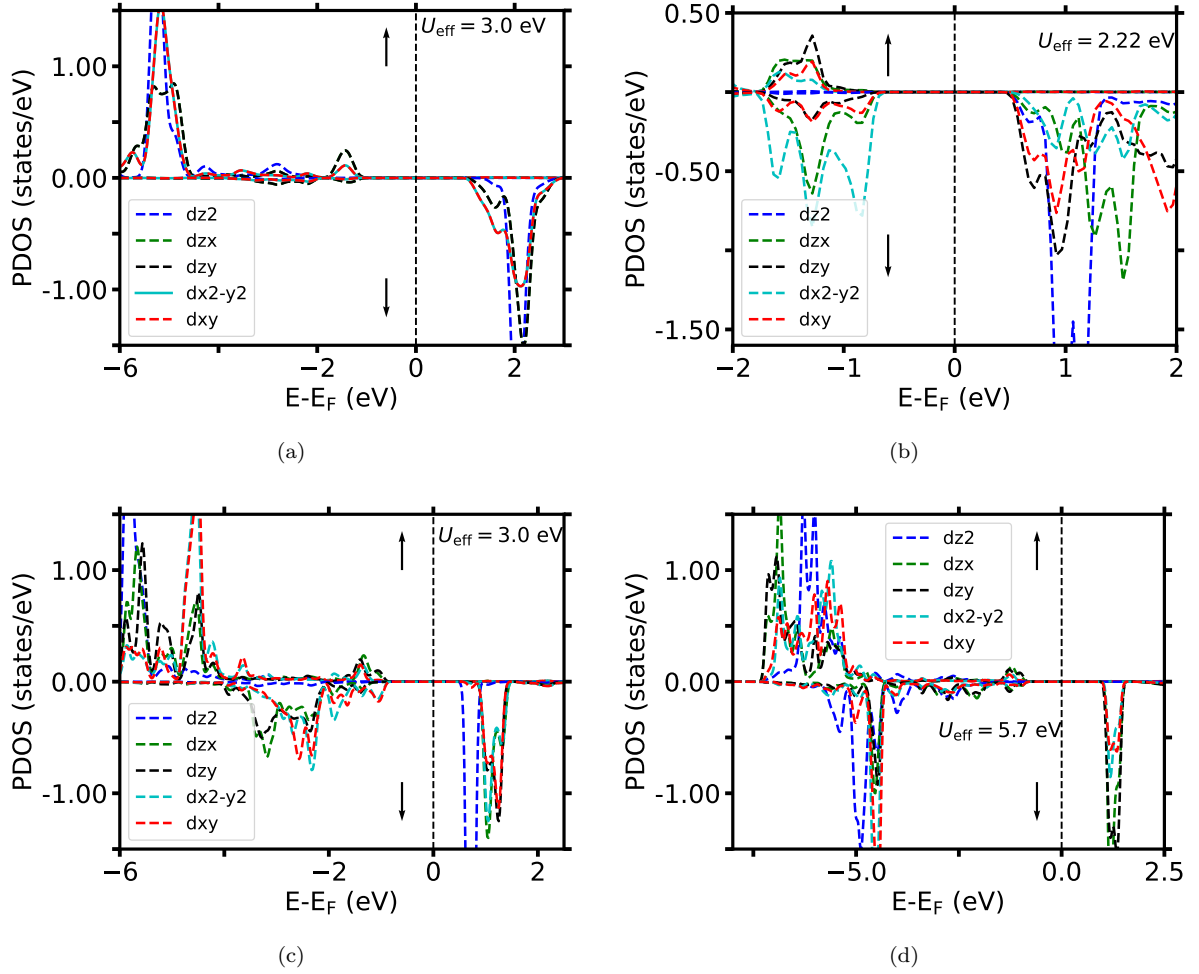

Figure 4: Orbital-resolved electronic density of states for (a) MnPS_3 , (b) FePS_3 , (c) CoPS_3 and (d) NiPS_3 monolayers. We consider the ground-state spin pattern for each material. For these calculations, we consider one atom of each species and plot the DOS for spin-up (up arrow) and spin-down (down arrow). The spin-up direction is defined by the majority spin of the magnetic ion selected for the plot.

Figure 5: Order parameter versus temperature (a,b) with, and (c) without bi-quadratic exchange interaction. Without the B -term, the critical temperature is by 73, 67.7, and 70.6 K for Mn, Co, and Ni, respectively. (b) shows the effect of increasing Δ on the order parameter of MnPS_3 .

In addition, the t term is controlled by the level of hybridization. For MnPS_3 , the hybridization is stronger as compared to other materials, that's why J_1 is larger than other materials (Tab. III).

Here, we study the effective spin Hamiltonian for MPS_3 monolayers. In our investigation, we calculate the effective spin Hamiltonian, aiming to identify the ground state in large simulation cells and to analyze the finite-temperature properties of M ($= \text{Mn, Fe, Co, Ni}$) PS_3 monolayers. Fig. 1 illustrates the various exchange interactions according to distances between magnetic ions and Tab. III reports their values (in meV, for $|S| = 1$), as well as the optimum value of U_{eff} (effective Coulomb interaction) in eV used for each compound. Notably, the geometry optimization performed at the start of our calculations shows that the distances between neighboring M atoms are sufficiently distinct only in the case of FePS_3 . This is why distinct first-neighbor interactions (J_{1a} and J_{1b}) are determined only for Fe, whereas Mn, Co, and Ni can be described with one unique first nearest-neighbor exchange interaction. Since J_4 is found to be considerably smaller than the other interactions, we can assume that the Heisenberg Hamiltonian is converged with respect to the interaction range considered. Interestingly, the parameter J_3 that connects parallel chains of the honeycomb lattice is always negative, i.e. AFM exchange is preferred. The absolute value of J_3 increases when going from Mn over Fe and Co to Ni, as already noticed earlier²⁷. Thus, the tendency to AFM chain interactions is found to increase with d-band filling. The same trend is observed for the biquadratic coupling; it increases toward the end of the transition metal series. However, the values reported in Tab. III refer to effective spins normalized to $|S| = 1$, while the size of the magnetic moment decreases along the transition metal series from Mn to Ni. Therefore, the single-ion anisotropy is found to be the largest for Fe. As we pointed out earlier, we attribute this finding to the unusually large orbital magnetic moment in Fe²⁴.

MnPS_3 emerges as an almost ideal antiferromagnetic (AFM) monolayer. This is concluded from J_1 and J_3 being both negative, a characteristic of the Néel-type antiferromagnetism. In absolute terms, J_1 is significantly larger for MnPS_3 than the more long-ranged interactions. Thus, the behavior of MnPS_3 is in line with the general expectations for magnetic insulators and makes this material distinct from the others. The small next-nearest neighbor interaction J_2 would prefer antiparallel coupling, but is frustrated in the Néel-type ground state. In the remaining three materials, FePS_3 , CoPS_3 and NiPS_3 , the dominant role of J_3 results in a magnetic ground state formed by zig-zag chains that are coupled antiferromagnetically to each other. The spins along the chains are aligned ferromagnetically, which is favorable due to the positive values of J_1 for Co and Ni. While in CoPS_3 and NiPS_3 the spin chains may run in any of the three directions compatible with the honeycomb lattice, two specific directions of the spin chain relative to the crystal

lattice are selected by the distinct values of J_{1a} and J_{1b} : the 'long bond' between two neighbor Fe atoms is part of the FM chain, as J_{1b} favors FM interaction. The spin orientation alternates from one chain to the next (as in CoPS_3 and NiPS_3) to satisfy the antiparallel inter-chain coupling dictated by J_3 in all transition metal phosphosulfides considered here.

It is widely recognized that the mere consideration of bilinear Heisenberg exchange interactions falls short in accurately describing the magnetic behavior of complex materials²⁸. In scenarios devoid of spin-orbit coupling, the most consequential higher-order term emerges as the bi-quadratic term, delineated as the fourth-order perturbation within the framework of the Hubbard model²⁹. Notably, a positive B term predominantly facilitates the emergence of noncollinear spin configurations; conversely, a negative B value is instrumental in engendering collinear ground states. For the family of MPS_3 materials, empirical evidence substantiates the collinear nature of the magnetic ground states, corroborated by the observation of negative B terms. These findings are systematically documented in Tab. III. Specific attention is bestowed upon FePS_3 , owing to the proximal spatial arrangement of its first nearest neighbors, necessitating the calculation of both ($B_{1a} = -2.10$ meV) and ($B_{1b} = -1.22$ meV). To elucidate the influence of the B term on the critical temperature and order parameter of MPS_3 materials, MC simulations were meticulously conducted with B set to zero. The resultant critical temperatures, adjusted in light of the removal of B , are presented in parentheses in Tab. III. The omission of the B term precipitates a diminution in the critical temperature, attributable to the attenuation of exchange coupling's capacity to counterbalance thermal fluctuations.

The presentation of the results concerning the order parameters of Néel and short-bond zigzag orders, as derived from the spin Hamiltonian (Eq. (1)), is illustrated in Fig. 5. It is noted that the definition of the order parameter for long-bond zigzag order in FePS_3 is not feasible through classical MC simulations without incorporating spin-phonon coupling²⁴. For the elements Mn, Co, and Ni, the observed transitions exhibit characteristics akin to those of the Kosterlitz-Thouless transition, attributed to the relatively weak single-ion anisotropy. Conversely, FePS_3 demonstrates a strong out-of-plane easy-axis anisotropy, aligning its behavior more closely with that predicted by the Ising model. The Monte Carlo simulations underscore the insufficiency of the B -term alone to significantly alter the order parameter (or the magnetic ground state spin pattern). However, they do indicate a significant increase of the critical temperature if the B -term is included.

Regarding the calculated values for single-ion anisotropy, these are detailed in Tab. III. The necessity of employing GGA+ U +SOC for these calculations is highlighted, emphasizing the pivotal role of the orbital moment. As summarized in Tab. II, which categorizes each system's spin and orbital moments as

per GGA+ U +SOC calculations, Fe exhibits the largest orbital moment, thus signifying considerable Δ . This is plausible given Fe's electronic configuration ending at $3d^6$. Conversely, Mn, with a closed-shell configuration ($3d^5$), exhibits an almost negligible orbital moment. The smallness of the energy scale associated with Δ is also evidenced by the possibility of a spin-flop transition^{30,31} in this material. To elucidate the orientation of the easy-axis for each material, we analyze the lattice vectors as depicted in Fig. 1, calculating the total energies utilizing the GGA+ U +SOC method. Our calculations confirm that for Fe-based systems, the easy-axis aligns with the c -direction, perpendicular to the $a-b$ plane. In contrast, for Co and Ni, the easy-axes are oriented along the b and a directions, respectively. In the case of Mn, the $a-b$ plane emerges as the easy plane, evidenced by the equal total energies for both a and b directions. Another consequence of SOC is the Dzyaloshinskii-Moriya interaction. As indicated in Tab. III, the D term is nonzero exclusively for Fe. This is attributed to the non-ideal honeycomb lattice structure of Fe-based systems, which lack inversion symmetry. Conversely, the other materials, characterized by an ideal honeycomb lattice, exhibit inversion symmetry, resulting in a zero D term.

Table III also includes the calculated critical temperatures (in K) obtained from Monte Carlo simulations. At low temperatures, these simulations converge to the AFM ground state of the respective material, i.e. Néel in MnPS_3 and chain-like in the other three compounds. From FePS_3 over CoPS_3 to NiPS_3 , we find a trend towards increasing ordering temperature T_N . Fig. 5 illustrates the order parameter of the magnetic ground state for MPS_3 . Following the Mermin-Wagner theorem⁹, the absence of anisotropic exchange interactions precludes the possibility of a thermodynamically stable phase transition and enduring magnetic order in two-dimensional systems. However, in this instance, the order parameter asymptotically approaches unity at low temperatures, yet exhibits an abrupt decline to zero, indicating a lack of well-defined stability. To address this, the strength of single-ion anisotropy of MnPS_3 was incrementally increased from 0.025 to 0.25 meV (Fig. 5b), analogous to the application of a magnetic field along the easy-axis direction. Consequently, it can be inferred that MnPS_3 , in its two-dimensional form, maintains a stable Néel ground state at low temperatures. To enhance this stability at elevated temperatures, the application of a magnetic field or an increase in the influence of single-ion anisotropy is necessitated.

IV. MAGNON SPECTRA

Starting from the spin Hamiltonian, Eq. (1), we calculated magnon spectra using the Holstein-Primakoff transformation and linearizing around the magnetic ground state of each compound. In this procedure, the bi-

quadratic term in the Hamiltonian is considered approximately via a renormalization of the nearest-neighbor Heisenberg couplings and the on-site anisotropy constant. More details of the calculations can be found in the appendix.

Results for MnPS_3 are shown in Fig. 6. For the Néel ground state, the crystallographic and the magnetic unit cell are identical (both hexagonal honeycomb lattice), and magnon dispersions are shown along the ΓK and ΓM path. Since both the single-ion anisotropy and the biquadratic term are small for this material, the zero-energy gap in the magnon spectrum is tiny (barely visible in the plot). Our result for the magnon spectrum of MnPS_3 can be compared with the spectra calculated by Olsen³² and by Bezazzadeh *et al.*³³. In their calculations, the magnon spectra reach their maxima at about 8 cm^{-1} if $U_{\text{eff}} = 5 \text{ eV}$ is used^{32,33}, and about 13 cm^{-1} ³², similar to ours, using $U_{\text{eff}} = 3 \text{ eV}$. This confirms the commonly observed trend that large U_{eff} leads to weaker magnetic interaction, and hence softer magnon spectra.

For FePS_3 , CoPS_3 and NiPS_3 that possess zig-zag chains as their magnetic ground state the magnetic unit cell is twice as larger as the crystallographic unit cell, i.e., it contains four transition metal atoms. Consequently, the magnon spectra of these materials, shown in Fig. 7, develop two branches. The lower branch does not reach zero at the small wavevector, as one would expect for 'acoustic' FM magnons; the sizeable gap in the magnon spectra at Γ even increases in size when going from Fe to Co to Ni. From our calculated exchange interactions, we conclude that the increasing biquadratic coupling term is mostly responsible for opening this gap. We note that such a gap is known to give rise to a logarithmic correction to the magnetic ordering temperature, see e.g. Ref. 28. The upper and the lower magnon branches show large splitting along ΓY which increases from Fe to Ni. This dispersion reflects the AFM coupling between the chains of parallel spin; its size is mostly governed by the exchange constant J_3 that increases along the transition metal sequence, as evidenced by the data in Tab. III. The direction ΓX in the spectra reflects the dispersion along the chains of parallel spin. The spectra for FePS_3 , the material with the 'long-bond' zigzag ground state, shows marked difference to CoPS_3 and NiPS_3 that have isotropic nearest-neighbor exchange $J_{1a} = J_{1b}$. In FePS_3 , one observes an avoided crossing of the two magnon branches along ΓX . This occurs because the interactions J_{1a} and J_{1b} that couple the parallel spins in the zig-zag chain have opposite sign. As a consequence, the energy of the upper branch at Γ goes below the lower branch when reaching X , and vice versa for the lower branch starting at Γ that rises in energy.

Recently Yan *et al.*³⁴ calculated magnon spectra *in bulk samples* for all four compounds studied here on the basis of a bi-linear Hamiltonian with exchange interactions up to the third neighbor shell. This means the forth neighbor interactions were not taken into consideration; moreover, they found a relatively large single-

Figure 6: Magnon spectrum for MnPS_3 in the Néel state. To the right, the path in the Brillouin zone is shown both for the zig-zag chain (top) and the Néel (bottom) structure.

ion anisotropy but ignored biquadratic interactions. The range of dispersion of the magnons predicted by them is in reasonable agreement with our magnon spectra, although details are different. This could be due to the difference in the magnetic ground state used as the starting point (Yan *et al.* did not distinguish between 'long-bond' and 'short-bond' zig-zag chains), or due to differences between the bulk and the monolayer.

Finally, we compare our calculated magnon spectra of monolayers to experimentally observed spectra from neutron diffraction at bulk materials. For MnPS_3 , we find overall good agreement with the experimental spin wave dispersion published in Ref. 35. In this neutron diffraction study, the spin waves reach their maximum energy at 11.5 meV, very close to our result of 12 meV. The observed magnon gap at the Γ -point is small, less than 0.5 meV, thus confirming the very small value of the magnetic anisotropy found in our calculations. Moreover, a recent neutron spectroscopy study³⁶ showed that the DMI in this material is negligibly small, which matches with our calculations.

For FePS_3 , the neutron diffraction data²³ shows a magnon branch starting at 17 meV dispersing downward to about 15 meV and then bending up again. Because of the incipient downward dispersion, we believe that this is the upper branch in our calculated spectrum. The lower branch may have escaped detection because the time-of-flight detection of the neutrons has a cut-off at low energy. In a later analysis of the experimental data by the same group³⁷, an improved fit of the data has been obtained by invoking a biquadratic coupling, albeit with a smaller exchange constant K than calculated by us. The experimental fit resulted in a very large single-ion anisotropy of about 2.5 meV to explain the magnon gap, whereas our theoretical description works with a much smaller $\Delta = -0.89\text{meV}$ and explains the magnon gap by a relatively large value of K which effectively renormalizes the anisotropy. Moreover, we speculate that the branches at higher energy (up to 40 meV)

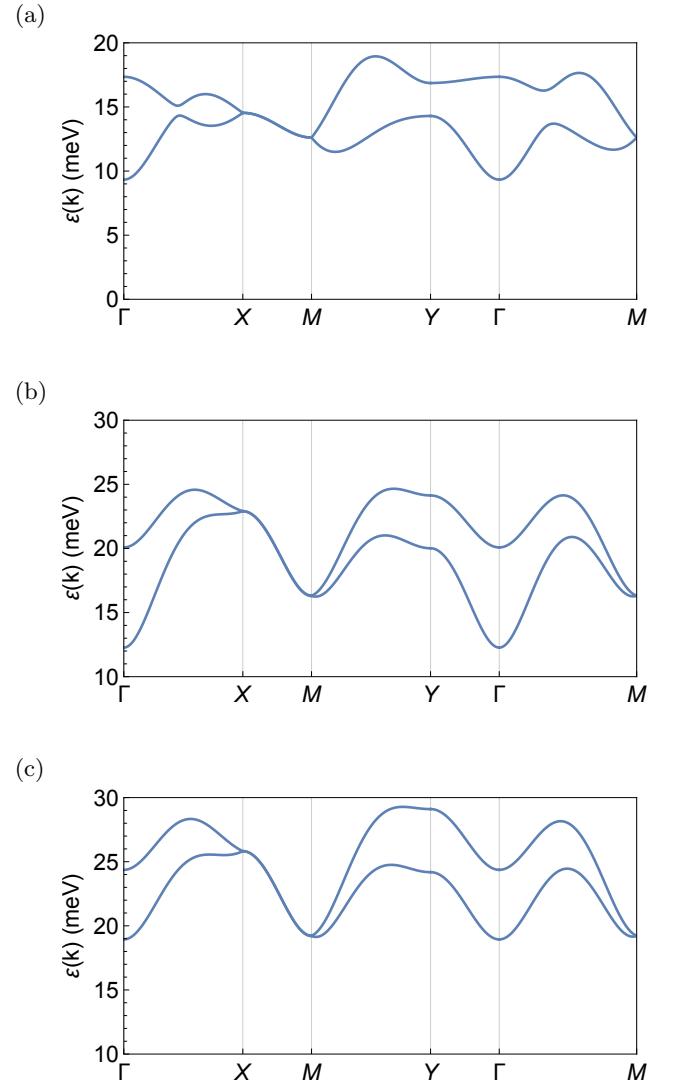

Figure 7: Magnon spectra for (a) FePS_3 in the long-zigzag chain AFM state, (b) CoPS_3 in the short-zigzag chain AFM state, (c) NiPS_3 in the short-zigzag chain AFM state. For all materials, zig-zag chains of parallel spins run along ΓX .

detected in the neutron scattering experiment are mixed phonon-magnon branches with a small magnon admixture, since according to our calculations FePS_3 does not support such hard pure magnon modes. A hybridization of magnon and phonon excitations in FePS_3 has been proposed recently^{38–40} on theoretical grounds.

For CoPS_3 , inelastic neutron scattering^{41,42} detected magnonic losses at 15 meV and 33 meV. The lower value is in the range where our calculation predicts a magnon branch. The experimentally observed upper branch might again result from a hybridization with phonons.

For NiPS_3 , inelastic neutron scattering⁴³ detected losses both below 10 meV and in the 40 to 50 meV range. A magnon model fitted to experimental neutron diffrac-

tion data⁴³ placed the magnon bands in the range of 8 meV, dispersing up to 50 meV. This is rather different from the magnon spectra presented here, which start at higher energy (18 meV) but then show less dispersion, reaching up to 28 meV. The reason for the disagreement is presently not understood.

V. CONCLUSION

In conclusion, this study offers a detailed examination of the magnetic properties of MPS_3 2D materials, utilizing the DFT+ U +SOC approach and Monte Carlo simulations. It highlights significant findings in the understanding of Heisenberg couplings, biquadratic and Dzyaloshinskii-Moriya interactions, and single ion anisotropy across various MPS_3 compounds. Since these materials are 3D magnetic semiconductors, applying the Hubbard parameter is essential to enhance the electron-electron correlations. The optimum U parameters have been chosen as 3.0 eV for Mn, 2.22 eV for Fe, 3.0 eV for Co, and 5.57 eV for Ni, respectively. Although magnetic ions form a hexagonal lattice in all materials, the way electrons fill the d shells of these ions results in different spin patterns in the ground state. The geometry optimization reveals that only in the case of $FePS_3$, there is a distortion from the ideal hexagonal lattice configuration. Specifically, the Fe-Fe distances between nearest neighbors vary by 0.14 Å. Due to this distortion, we calculate two different biquadratic exchange terms along the longer and shorter bond distances.

To clarify the importance of the biquadratic exchange for these materials, we conduct Monte Carlo simulations both with and without the biquadratic term. Our results indicate that the absence of the biquadratic term leads to a reduction in the Néel temperature and alters the order parameter, which signifies the spin-spin correlation. Specifically, the order parameter undergoes a transition from 1 (indicating long-range order) to 0 (indicating a paramagnetic phase) at lower temperatures. In $MnPS_3$, this effect is less pronounced due to a smaller biquadratic term. $MnPS_3$, with its Néel ground state, behaves like a typical magnetic semiconductor where the exchange interaction parameters (J) decrease with increasing distances. Additionally, the Néel temperature obtained from MC simulations is 73.6 K, which closely aligns with the experimental value of 78 K observed in the bulk system. However, for other materials that feature AFM zigzag chains, the third-nearest-neighbor exchange interaction (J_3), which connects these chains, is crucial for stabilizing the zigzag ground state, especially in the case of $NiPS_3$. Spin-orbit coupling effects, particularly single-ion anisotropy and Dzyaloshinskii-Moriya interactions, along with orbital moment ($0.77 \mu_B$), are most pronounced in Fe due to the electronic configuration of Fe^{2+} which ends up as $3d^6$. For other materials, the Dzyaloshinskii-Moriya interaction values are nearly zero, and the orbital moments are 0.02, 0.11, and 0.22

μ_B for Mn, Ni, and Co, respectively. Consequently, the strength of the single-ion anisotropy in these materials follows a trend similar to that of the orbital moments. Moreover, the biquadratic interactions significantly enhance the gaps in the magnon spectra of Fe, Co and Ni compounds.

VI. ACKNOWLEDGMENT

We gratefully acknowledge the computing time granted by the Center for Computational Sciences and Simulation (CCSS) of the University of Duisburg-Essen and provided on the supercomputer magnitUDE (DFG Grant No. INST 20876/209-1 FUGG and INST 20876/243-1 FUGG) at the Zentrum für Informations- und Mediendienste (ZIM). M. A. was supported by a fellowship from Universität Duisburg-Essen.

Appendix A: Derivation of the spin Hamiltonian

a. Derivation of the Heisenberg term The exchange parameters of the Heisenberg model as detailed in Eq. (2) are determined by fitting to total energies obtained for the ions fixed at their previously determined, materials-specific ground state positions, but varying collinear spin configurations, similar to our previous work²⁴. We analyze a supercell configuration of dimensions $2 \times 2 \times 1$, comprising 40 ions that include 8 magnetic atoms, alongside 8 phosphorus and 24 sulfur ions. Analytical calculations permit the determination of distances between magnetic atoms extending to the fourth-nearest neighbors. Each category of nearest neighbor interaction is associated with a corresponding exchange coupling constant, denoted as J . It is pertinent to mention that in our analytical derivations, the magnitude of the spin, $|S|$, is set to 1, which simplifies the calculation of the exchange parameter J .

Prior to conducting Density Functional Theory augmented with Hubbard U (DFT+ U) calculations, up to 15 collinear spin configurations are postulated, and their total energies are computed analytically. Here, ferromagnetic (FM) interactions among nearest neighbors contribute a value of $+1/2$, whereas antiferromagnetic (AFM) interactions contribute a value of $-1/2$. Subsequently, the total energies for these configurations are quantitatively assessed using the DFT+ U method. By employing a least-squares fitting technique, the low-lying energies are mapped onto the previously derived analytical expressions, thereby facilitating the extraction of the J parameters.

b. Derivation of the biquadratic term To derive the biquadratic exchange term, B , it is necessary to analyze noncollinear configurations where the contributions from the Heisenberg exchange term in the total energy differences are degenerate. To achieve this, we consider a $2 \times 1 \times 1$ supercell configuration, comprising 20 atoms with

4 magnetic ions. The spins of the first and last magnetic ions are held fixed, while the orientations of the spins of the intervening magnetic ions are rotated such that the sum of their spins equals zero, i.e., $S_i + S_j = 0$. This configuration ensures that the observed variations in total energy are solely attributable to the biquadratic term, B . For the specific case of FePS₃, to calculate the biquadratic term B_{1b} , we adopt a similar strategy but utilize a $1 \times 2 \times 1$ supercell. Here, the spatial arrangement of the atoms within the supercell is designed such that the distances between the intermediate atoms correspond to d_{1b} . This approach enables the isolation of the biquadratic exchange contributions from other magnetic interactions within the system.

$$H_B = B \sum_{n,n} (\vec{S}_i \cdot \vec{S}_j)^2 \quad (\text{A1})$$

c. Derivation of the anisotropic terms For the evaluation of anisotropic terms, all calculations are conducted using the primitive cell, which comprises 10 atoms with 2 magnetic ions. To deduce the strength of the Dzyaloshinskii-Moriya interaction (DMI), it is essential to consider the influence of spin-orbit coupling (SOC). The computational framework utilized for these calculations is GGA+ U +SOC. Within this framework, we need to select magnetic configurations in such a way that the differences in total energies primarily reflect the effects of SOC, while the contributions from single-ion anisotropy after SOC and other interactions before SOC are rendered degenerate. We examine two distinct magnetic configurations. In the first configuration, the orientations of the spins are aligned along the a -axis and the negative b -axis. In the second configuration, the spins are aligned along the a -axis and the positive b -axis. The total energy differences of these two configurations can be attributed to DMI.

For the determination of single-ion anisotropy (SIA), we analyze a pair of magnetic configurations wherein all spins are aligned with either the easy-axis or the hard-axis. These orientations are strategically chosen to ensure the cancellation of the DMI within the framework of GGA+ U +SOC calculations. Consequently, the differences in total energies observed between these configurations can be exclusively attributed to the effects of SIA. It should be noted that the total energies of the two configurations are the same before considering SOC, indicating the degeneracy of isotropic terms.

$$H_{\text{aniso}} = D \sum_{n,n} \hat{D}_{ij} \cdot (\vec{S}_i \times \vec{S}_j) + \Delta \sum_i (\vec{S}_i \cdot \vec{d}_i)^2 \quad (\text{A2})$$

Appendix B: Calculation of magnon spectra

a. Bosonisation We define spin operators $\hat{\mathbf{S}} = (\hat{S}^x, \hat{S}^y, \hat{S}^z) = (\frac{1}{2}(\hat{S}^+ + \hat{S}^-), \frac{1}{2}(\hat{S}^+ - \hat{S}^-), \hat{S}^z)$ at lattice

site j via bosonic creation and annihilation operators

$$\begin{aligned} \hat{S}_j^+ &= \sqrt{2S - \frac{\hat{b}_j^\dagger \hat{b}_j}{2S}} \hat{b}_j, \\ \hat{S}_j^- &= \hat{b}_j^\dagger \sqrt{2S - \frac{\hat{b}_j^\dagger \hat{b}_j}{2S}}, \\ \hat{S}_j^z &= S - \hat{b}_j^\dagger \hat{b}_j \end{aligned}$$

For sufficiently large $|S|$, it is sufficiently accurate to use a Taylor expansion of the square root to lowest order, yielding

$$\begin{aligned} \hat{S}_j^+ &\approx \sqrt{2S} \hat{b}_j, \\ \hat{S}_j^- &\approx \hat{b}_j^\dagger \sqrt{2S}, \\ \hat{S}_j^z &= S - \hat{b}_j^\dagger \hat{b}_j. \end{aligned}$$

For a detailed calculation of the Hamiltonian in terms of the \hat{b} and \hat{b}^\dagger operators, we refer to Kartsev *et al.*, Ref. 28, supplementary section 15. A Fourier transformation of the operators \hat{b} and \hat{b}^\dagger is performed for each inequivalent lattice site, and consequently the operators acquire an additional index k .

Figure 8: Supercell used to calculate magnons of materials with ferromagnetic zigzag chains as ground state. There are two chains, 1-4-1-4... and 2-3-2-3..., that are antiparallel to one another.

In a honeycomb lattice, there are two inequivalent lattice sites, and if the Neel ground state is considered, these two sites are sufficient. For those systems that display zig-zag chains as their ground state, we use a supercell containing four transition metal atoms, as shown in Fig. S1. The Hilbert space of the spins of the four atoms is spanned by the vector

$$\Psi_{\mathbf{k}} = (b_{1,\mathbf{k}}, b_{3,-\mathbf{k}}^\dagger, b_{4,\mathbf{k}}, b_{2,-\mathbf{k}}^\dagger, b_{1,-\mathbf{k}}^\dagger, b_{3,-\mathbf{k}}, b_{4,-\mathbf{k}}^\dagger, b_{2,\mathbf{k}})$$

The first indices of the operators refer to the atoms numbered in Fig. S1. Note that, in case of FePS₃, the long bond (with interaction J_{1b}) is between atoms 2 and 3.

b. Renormalization of interactions due to biquadratic term The biquadratic term, coupling two neighboring atomic sites i and j , is approximated by

$$(\mathbf{S}_i \cdot \mathbf{S}_j)^2 \approx 2S^3(b_i^\dagger b_j + b_i b_j^\dagger - 3b_i^\dagger b_i - 3b_j^\dagger b_j) + S^4, \quad (\text{B1})$$

retaining the highest powers in $|S|$.

The Hamiltonian H_{spin} in Eq. (1) has on-site and nearest-neighbor terms, in addition to the more long-ranged terms in the Heisenberg Hamiltonian. The Dzyaloshinskii-Moriya interaction between nearest neighbors is very small; in fact it vanishes due to symmetry if all nearest neighbor bonds have the same length. Therefore we can disregard the canting of spins.

Both the biquadratic term and the Heisenberg terms J_{1a} and J_{1b} run over nearest neighbors; using the approximation (B1) it is therefore possible to merge them by introducing

$$\begin{aligned} \tilde{J}_{1a} &= J_{1a} + BS^2 \\ \tilde{J}_{1b} &= J_{1b} + BS^2 \\ \tilde{\Delta} &= \Delta + 3BS^2 \end{aligned}$$

Note that \hat{S}_z invokes an on-site operator product $b_i^\dagger b_i$; this is why the on-site anisotropy Δ needs to be renormalized, too. The factor 3 appearing in the above equation stems from the 3 nearest neighbors.

With these transformations, the Hamiltonian is brought to the bilinear form

$$H_{\text{spin}} = -\frac{1}{2} \sum_{\mathbf{k}} \Psi_{\mathbf{k}}^\dagger H(\mathbf{k}) \Psi_{\mathbf{k}} + H_0 \quad (\text{B2})$$

c. Holstein-Primakoff Hamiltonian In the following, we refer to the renormalized case with $|S| = 1$, as in the main text of the manuscript. For zig-zag chains, a supercell containing four magnetic ions, Fig. S1, is used. For notational brevity, we rescaled the \mathbf{k} -vector to match the square-shaped Brillouin zone, $k_x a \mapsto k_x$, $k_y a \sqrt{3} \mapsto k_y$ with a being the lattice constant. After the bosonisation of the four spin operators, the Hamiltonian can be expressed by a (8×8) matrix (see Ref.⁴⁴)

$$H(\mathbf{k}) = \begin{pmatrix} h(\mathbf{k}) & 0 \\ 0 & h^T(-\mathbf{k}) \end{pmatrix} \quad (\text{B3})$$

The two blocks on the diagonal are given by (4×4) matrices $h(\mathbf{k})$ with

$$h(\mathbf{k}) = \begin{pmatrix} d(\mathbf{k}) & \gamma(\mathbf{k}) \\ \gamma^\dagger(\mathbf{k}) & d(-\mathbf{k}) \end{pmatrix} \quad (\text{B4})$$

For the long zig-zag phase, e.g. in FePS₃, the entries are expressed using Pauli's $(2 \times 2)\sigma$ -matrices

$$\begin{aligned} d(\mathbf{k}) &= \sigma_0(\tilde{\Delta} - \tilde{J}_{1b} + 2J_2 + 3J_3 - 2J_4 - 2D \sin k_x + 2J_2 \cos k_x) \\ &\quad + \sigma_1[4 \cos(k_y/2)(D \sin(k_x/2) + J_2 \cos(k_x/2))] \\ \gamma(\mathbf{k}) &= \sigma_0[(\tilde{J}_{1a} + \tilde{J}_{1b})e^{ik_y/6} \cos(k_x/2) + 2J_4(e^{-5ik_y/6} \cos(k_x/2) + e^{ik_y/6} \cos(3k_x/2))] \\ &\quad + \sigma_1[2J_3 \cos k_x + J_3 e^{ik_y} + 2J_4 e^{ik_y} \cos k_x + \tilde{J}_{1a}] e^{-ik_y/3} \end{aligned}$$

For the short zig-zag phase, e.g. in CoPS₃ and NiPS₃, we have

$$\begin{aligned} d(\mathbf{k}) &= \sigma_0(\tilde{\Delta} - 2\tilde{J}_{1a} + \tilde{J}_{1b} + 2J_2 + 3J_3 - 2J_4 - 2D \sin k_x + 2J_2 \cos k_x) \\ &\quad + \sigma_1[4 \cos(k_y/2)(D \sin(k_x/2) + J_2 \cos(k_x/2))] \\ \gamma(\mathbf{k}) &= \sigma_0[2\tilde{J}_{1a} e^{ik_y/6} \cos(k_x/2) + 2J_4(e^{-5ik_y/6} \cos(k_x/2) + e^{ik_y/6} \cos(3k_x/2))] \\ &\quad + \sigma_1[2J_3 \cos k_x + J_3 e^{ik_y} + 2J_4 e^{ik_y} \cos k_x - \tilde{J}_{1b}] e^{-ik_y/3} \end{aligned}$$

To calculate the magnon spectrum, we use the method described in Ref. 33: First, we calculate the Cholevsky decomposition of $h(\mathbf{k})$, i.e. we calculate the square matrix $R(\mathbf{k})$ with the property $h(\mathbf{k}) = R^\dagger(\mathbf{k})R(\mathbf{k})$. A matrix with both positive and negative eigenvalues is con-

structed by $X(\mathbf{k}) = R(\mathbf{k})\hat{\phi}R^\dagger(\mathbf{k})$, where $\hat{\phi}$ is the so-called para-unitary matrix, i.e., a diagonal matrix with alternating entries of 1 and -1 , $(\hat{\phi})_{ij} = (-1)^j \delta_{ij}$. The positive eigenvalues $\varepsilon(\mathbf{k})$ of $X(\mathbf{k})$ can be interpreted as the frequencies of the magnon branches; the spin pattern be-

longing to the modes can be obtained from

$$\Psi_{\mathbf{k}} = R^{-1}(\mathbf{k})U(\mathbf{k})(\hat{\phi}L(\mathbf{k}))^{1/2}$$

Here L is a diagonal matrix obtained as $L(\mathbf{k}) = U^\dagger(\mathbf{k})X(\mathbf{k})U(\mathbf{k})$ with the unitary matrix U . Hereby, the columns and row of U should be arranged in such a way that the sign of the eigenvalues alternates, in the same way as the diagonal elements of $\hat{\phi}$ alternate in sign.

d. Neel antiferromagnet In this case, that applies to MnPS_3 , the calculation of the magnon modes is much simpler. Only two magnetic ions per unit cell are required. The unitary transformation $U(\mathbf{k})$ can be written down explicitly. Alternatively, one may skip the para-unitary matrix, and use a Bogoliubov transform combining the operators \hat{b} and \hat{b}^\dagger of the two sublattices (instead of a unitary transform), see e.g. Ref. 32, appendix. The final expression for the magnon mode reads in this case

$$\begin{aligned} \varepsilon(\mathbf{k}) &= \\ &= -S \left[(-\tilde{\Delta} + 3\tilde{J}_1 + (\gamma_2(\mathbf{k}) - 6)J_2 + 3J_3) \sqrt{1 - |\tilde{\gamma}(\mathbf{k})|^2} \right] \end{aligned}$$

with

$$\tilde{\gamma}(\mathbf{k}) = \frac{\tilde{J}_1\gamma_1(\mathbf{k}) + J_3\gamma_3(\mathbf{k})}{3\tilde{J}_1 + (\gamma_2(\mathbf{k}) - 6)J_2 + 3J_3 + (\gamma_4(\mathbf{k}) - 6)J_4}$$

and

$$\gamma_j = \sum_{j=1}^{\text{NN}(j)} e^{i\mathbf{k} \cdot \mathbf{R}_j}$$

Here $\text{NN}(j)$ is the number of neighboring magnetic ions in the j th neighbor shell, and the \mathbf{R}_j are the positions of these atoms.
